WORKING PAPER NO. 3

TECHNOLOGY AND CHANGES IN SKILL STRUCTURE: EVIDENCE FROM SEVEN OECD COUNTRIES*

May 1998 - Revised

Stephen Machin and John Van Reenen

Abstract
Much of the dramatic change in skill and wage structure observed in recent years in the United States is believed to stem from the impact of new technology. This paper compares the changing skill structure of wage bills and employment in the United States with six other OECD countries - the United Kingdom (where wage inequality rose even faster in the 1980s than in the United States), two Continental European countries (France and Germany), two Scandinavian countries (Denmark and Sweden) and Japan. We investigate whether a directly observed measure of technical change (R&D intensity) is able to account for the growth in the importance of more highly skilled workers which has occurred in all countries. Evidence of a significant association between R&D intensity and skill upgrading is uncovered in all seven countries. These results provide evidence that skill biased technical change is an international phenomenon that has had a clear effect of increasing the relative demand for skilled workers.

Keywords: Employment; Wages; Skills; Technology; R&D.

JEL Classification: J51, O33.

* We would like to thank Thibaut Desjonqueres and Annette Ryan for their exceptional research assistance on this paper (and its earlier versions). We have received a great deal of help with data from many people, notably Jean Bourdon, Richard Dickens, Par Hansson, Mary O' Mahony, Souichi Ohta, George Papaconstantinou, Marcus Rebick and David Wilkinson. We would like to thank Olivier Blanchard, Lawrence Katz and two referees for a number of helpful comments. In addition, Susanne Ackum-Agell, Eric Bartelsman, Eli Berman, Richard Blundell, Richard Dickens, Zvi Griliches, Daniel Hamermesh, Jonathan Haskel, Stephen Nickell, Andrew Oswald, John Schmitt and participants in numerous seminars have offered useful suggestions. Financial assistance has come from the Leverhulme Trust and the Economic and Social Research Council.

I. INTRODUCTION

The structure of wages and employment has dramatically shifted in many countries in recent years. There have been big increases in wage inequality in the United States and in the United Kingdom, whilst other countries (especially those in continental Europe) have had more stable wage structures. At the same time unemployment has risen sharply in several European countries and almost all countries have seen shifts in employment structure that have adversely affected relatively unskilled workers.

Many commentators believe that much of the change in skill and wage structure in the United States stems from the impact of new technology. Indeed, it has been argued by a large body of economists (e.g. Bound and Johnson [1992]; Berman, Bound and Griliches [1994]; Johnson [1997]) that certain skill-biased technological changes (SBTC) have favored the wage and employment prospects of relatively skilled workers, whilst simultaneously damaging the wages and employment of the less skilled. Furthermore, if one considers relative employment shifts in the manufacturing sectors of a number of advanced countries one sees a similar pattern to that observed in the United States, in that the share of relatively skilled workers in total wage costs and employment appears to have increased (see Berman, Bound and Machin [1998]). Most of these shifts appear to have occurred within, rather than between industries, leading some commentators to come down in favor of SBTC as the key factor underpinning shifts in relative labor demand.

A difficulty with some of this work is that the effects of technology are inferred as indirect effects associated with particular correlation patterns, or linked to specific components from decompositions, rather than being based upon directly observed comparable measures of technical change across countries. In this paper we consider whether one directly observable indicator of technology, R&D intensity, is intrinsically associated with the degree of skill

upgrading. We adopt an international perspective by looking at the relationship between changes in skill structure and R&D for comparable data in seven OECD countries: the United States, the United Kingdom (where wage inequality rose even faster in the 1980s than in the United States, albeit from a much lower level), two Continental European countries (France and Germany), two Scandinavian countries (Denmark and Sweden) and Japan. To do so we construct an original industry level panel dataset from a wide variety of national and international sources.[1]

According to our analysis, there have been shifts in relative labor demand that have favored skilled workers in all seven countries and, as in the United States, most of this shift has occurred within, rather than between, industries. Evidence of a significant complementarity of human capital with new technology is uncovered in all seven countries and this is robust to alternative measures of skill and technology. We do not find that measures of trade, such as the share of imports originating from less developed countries, are important in explaining the change in within industry skill structures. Our main findings are robust to alternative econometric specifications which allow for the possible endogeneity of technical change and spillover effects.

Overall, our reading of these results is they provide evidence that skill biased technical change is an international phenomenon that has had a clear effect of increasing the relative demand for skilled workers. This should not be taken to mean that technology is the *only* factor in explaining the changing skill structures of the industrialized countries. We cannot deduce the full effect of technology on labour market structure without also closing the model by looking at supply side effects and the non-manufacturing sector, which is beyond the scope of this paper. Our view is that the results presented here form a necessary, but not sufficient, part of the story

---

[1] The focus on international comparisons using microeconomic data through time means that our work is closest in spirit to the recent comparison of wage and employment structures in the United States, Canada and France by Card, Kramarz and Lemieux [1996]. However, as will be seen below, we employ a somewhat different methodology.

that changes in the wage and employment distribution are closely tied to technical changes.

The plan of the paper is as follows. The next section describes the construction of the dataset and offers some preliminary descriptive statistics. Section III outlines the econometric strategy, and gives a discussion of the basic regression results. Section IV goes on to test the robustness of the results by examining other technology measures, the effects of trade, the potential endogeneity of R&D and international spillover effects. Some concluding remarks are made in section V.

II. DATA DESCRIPTION

A. Data Construction

We draw on a number of data sources to construct the industry-level panel data we use in our empirical analysis. The data on value added, investment, and technology comes from an industry-level panel dataset compiled by the OECD known as STAN (Standardized Analytical Database). This contains data which is internationally comparable having been compiled by OECD researchers working with the Central Statistical Offices of each country. The OECD also develops complementary databases to STAN. We use their Business Enterprise R&D (ANBERD) database for R&D data and the Bilateral Trade Database for international trade information.

STAN/ANBERD is the only dataset which contains information on industry-level R&D expenditures over time across industrialized countries. The industry R&D measure is comprised of the amount of R&D conducted by (but not necessarily financed by) the business sector and this is the key technology measure we rely upon. Of course, we acknowledge from the outset that it is well known that no single proxy for technology is perfect. However, when compared to other existing measures of innovation, R&D intensity has several advantages for the purposes of our study. First, it is measured in a broadly consistent way over time and across countries. Most

industrialized nations use the Frascati manual definition of R&D and the OECD statisticians have made considerable efforts to make the measures consistent over time across the countries we consider.[2] Although a measure of investment in computers or information technology may have some advantages over R&D these are generally only available for the United States and even then only for a few recent years. Secondly, R&D is measured in 'dollar terms' (or D-Marks, or pounds, etc). Most measures of innovation such as patents or innovation counts are qualitative in nature. The proportion of workers using a computer does not adjust for the differential amount of resources going into purchasing a computer, for example. Thirdly, it is a direct measure of technology, unlike total factor productivity (TFP) which has the twin disadvantages of being highly endogenous and containing a variety of unknown influences unrelated to technology (such as unmeasured changes in the factor quality mix). Finally, more on the downside, R&D has the potential drawback that it is only an input (as are the physical investment flows we use to construct the fixed capital stock). Yet, even here, a long line of research has established that R&D expenditures do a reasonably good job at proxying the outputs of the innovative process.[3]

In terms of data on skills, STAN only has data on total employment by industry and does not disaggregate by skill category. To overcome this, we drew on the United Nations Industrial Statistics Database (UNISD) which includes data on the wage costs and numbers of production and non-production workers by industry. Merging the datasets together left us with country-specific time series data on relative wage costs, employment and R&D for the same

---

[2] For a detailed discussion of the procedures used see OECD [1997a].

[3] For example, Griliches, Hall and Pakes [1987] have investigated the informativeness of the patent count measure in a dynamic factor model of firm value, R&D, sales and investment. They found that (with the exception of the pharmaceutical industry) patents provided little additional information on the economic variables above and beyond that contained in R&D spending.

manufacturing industries (defined at about the 2-digit level) in each country. From our data matching procedures (see the Data Appendix) there are actually 16 industries that make up the entire manufacturing sector in each country. However, when we need to consider the technology measures we analyse data on 15 industries, dropping the transport goods sector due to erratic R&D data. The sample of countries we use is dictated by the availability of data on skill structure and on R&D intensity. Full information on the matching and cleaning procedures and a listing of industries is given in the Data Appendix.

We have also generalized our empirical work in a number of directions. As one may have doubts about the use of the non-production/production worker distinction to proxy skill, we have also constructed education based measures by aggregating individual-level cross-sectional data sources to industry-level in France, Germany, Japan, the United Kingdom and the United States.[4] Despite problems of consistently defining education groups across countries, we have constructed education based employment shares at exactly the same industry-level as the combined STAN/UNISD data through time. In this paper we look only at high education employment shares, which correspond to the proportion of workers in an industry with a college degree.

B. Descriptive Statistics

Some descriptive statistics on the key variables for the manufacturing sectors of the seven countries between 1973 and 1989 are reported in Table I. The first point to note is that the non-production worker share of the wage bill has risen in all countries and that, in absolute terms, the largest increase has been in the United Kingdom and United States (with annualized increases of .6 and .5 percentage points per year) and the smallest in Sweden and Japan (both with

[4] The data sources used are: France - Enquete Emploi; Germany - Mikrozensus; Japan - Japanese Wage Census; UK - Labour Force Survey; US - Current Population Survey. Note that for Germany and Japan the data on non-production shares also comes from these sources and not from UNISD. More details are given in the Data Appendix.

annualized increases of about .25 percentage points per year). There is a similar pattern for employment shares, but one should notice that the United Kingdom and United States changes are less dramatic here and the size of the change is more in line with the other countries, due to the fact that wage differentials between non-production and production workers increased very rapidly in those two countries in the 1980s but remained relatively constant elsewhere. In the same way, more highly educated workers have increased their relative employment shares in the countries on which we have data on education. The descriptive statistics in Table I point to considerable shifts in skill structure that have favored more skilled workers.

The bottom panel of Table I also shows the pattern of R&D spending across the countries. In 1989 R&D intensity (R&D divided by value added) was highest in the US and lowest in Denmark. It is also interesting to note the time series pattern. All countries have increased the proportion of value added given over to R&D between 1973 and 1989, with the largest increases occurring in Japan and Sweden. More detailed analysis of the increasing R&D intensities reveals both an increasing importance of high tech industries and also a general increase in manufacturing R&D across almost all industries.[5]

As studied in much more detail in Berman, Bound and Machin [1998] the bulk of the change in skill proportions is going on within, rather than between, industries. Our disaggregated data on the 16 industries within manufacturing also allows a comparison of the within/between changes using education rather than occupation as a definition of skill. Figure I reports the familiar decomposition of aggregate changes in skilled wage bill and employment shares into

---

[5] Decomposing the change in manufacturing R&D intensity reveals that for Denmark, France, Germany, Japan and Sweden the `between' component (movement towards more high R&D industries) accounts for less than half of the aggregate change in R&D intensity. In the United Kingdom and the United States, however, between-industry restructuring accounts for more than half (see Van Reenen [1997]).

within industry and between industry components.[6] In all seven countries the vast majority of skill upgrading is happening within industries and this is true for both the occupational and educational proxies for skill.[7]

Berman, Bound and Machin [1998] also present empirical evidence that faster skill upgrading is concentrated in similar industries in different countries and argue that this is consistent with the idea that SBTC has had a pervasive effect in shifting relative labor demand in favor of skilled workers across countries. In our data we are able to break down the overall change in the non-production or education shares into each of the manufacturing sectors and then rank the industries by their within-industry contribution to the overall change. It is clear by just eyeballing these rankings that, for the most part, the biggest changes are concentrated in the same industries across countries. The industries with the biggest individual contributions are Computers and Non-Electrical Machinery, Professional Goods (i.e. Instruments) and Paper, Printing & Publishing. The existence of cross-country correlations of industry skill upgrading is important and suggests that a key empirical strategy should be to isolate what factors are common to the industries in which faster skill upgrading is concentrated. Yet it remains difficult to be fully convinced that these kinds of cross country industry correlations signify a SBTC shock in the

---

[6] The aggregate change in the skilled proportion over a given time period, ΔP, can be decomposed (for industries i= 1,2,.....N) as:

$$\Delta P = \sum_i \Delta S_i \overline{P_i} + \sum_i \Delta P_i \overline{S_i}$$

where $P_i = SK_i/L_i$ is the proportion of skilled workers in industry i and $S_i = L_i/L$ is the share of total employment in industry i. A bar over a variable denotes a time mean. The first term on the right hand side of the equation is the change in the aggregate proportion of skilled workers attributable to shifts *between* industries with different proportions of skilled workers. The final term in the expression is the change in the aggregate proportion of skilled workers attributable to changes in the proportion of skilled workers *within* industries.

[7] This pattern remains true in non-manufacturing sectors and also for more disaggregated industry definitions (see Machin and Van Reenen [1997]).

absence of direct measures of technology.[8]

That technical change is clearly a candidate for explaining the observed shifts is indicated by the fact that the same industries tend to be R&D intensive across countries. This is shown in Table II which reports cross-country correlations in industrial R&D intensity (only 15 industries are now considered because, as noted above, we drop the transport goods industry due to worries about the reliability of the R&D data). All pairwise correlations are positive, large in magnitude and significantly different from zero. This clearly mirrors the observation that faster skill upgrading is observed in similar industries in different countries, although the R&D correlations are clearly stronger than the skill upgrading correlations.[9] The latter suggests that other factors may also be at play. It is in the spirit of these data patterns that we next turn to regression models which essentially try to see whether it is in fact broadly the same industries that have simultaneously experienced skill upgrading and technical change.

---

[8] For example, recent work by Haskel and Slaughter [1998] has also emphasised that technical change may have effects on the between industry component as well as the within industry shifts in employment.

[9] The skill upgrading correlations in our data are in line with those in Berman, Bound and Machin [1998] even though our data is more aggregated (they consider 28 industries, as compared to our 15). For example, for the 12 possible pairwise comparisons of cross-country correlations in non-production wage bill shares (for Denmark, Japan, Sweden, the United Kingdom and United States), all were positive and 5 were statistically significant at the 5 percent level. For the 1980-90 time period, and for a wider range of countries, Berman, Bound and Machin [1998] report that 12 out of 36 cross-country correlations of changes in non-production wage bill shares were significant.

III. EMPIRICAL MODELS OF CHANGES IN SKILL STRUCTURE AND TECHNOLOGY

A. Econometric Approach

Beginning from a simple restricted variable translog cost function for industry i in country j in year t, say $C[\log(W^{NP})_{ijt}, \log(W^{P})_{ijt}, \log(K_{ijt}), \log(Y_{ijt}), TECH_{ijt}]$, it is straightforward to derive a non-production wage bill share equation as:

$$SHARE_{ijt} = \varphi_{ij} + \alpha_j \log(K_{ijt}) + \beta_j \log(Y_{ijt}) + \gamma_j TECH_{ijt} + \delta_j \log(W^{NP}/W^{P})_{ijt} \quad (1)$$

where SHARE is the non-production wage bill share, K is the tangible capital stock (assumed to be a fixed factor), Y is value added, W^{NP} and W^{P} are the wage rates of non-production and production workers and TECH is a measure of the stock of technology.[10] The j subscript attached to the coefficients allows them to vary across countries (although in practice we estimate separate equations for each country). We time difference equation (1) in order to sweep out the correlated industry specific fixed effects φ_{ij}. The stochastic form of the estimating equation (with Δ being a difference operator and u a random error term) is therefore:

$$\Delta SHARE_{ijt} = \alpha_j \Delta \log(K_{ijt}) + \beta_j \Delta \log(Y_{ijt}) + \gamma_j (R\&D/Y)_{ijt} + \eta_{jt} D_{jt} + u_{ijt} \quad (2)$$

Notice that the relative wage rates have been replaced by country specific time dummies (D_{jt}) which will also capture common macroeconomic shocks. The differenced industry specific relative wage terms could be entered separately in (2), but they are likely to be highly endogenous. In the absence of any convincing instruments, wages are assumed to move in tandem across the economy (levels are captured by the fixed effect). Some specification tests reported below relax this assumption and show the results to be robust to the inclusion or

---

[10] Notice that, in this framework, SHARE is the share of non-production worker wages in the overall wage bill, not total costs, as the only variable factors of production are the two labor types (since the capital and technology stocks are assumed quasi-fixed).

exclusion of the industry specific relative wage.

More importantly in terms of specification issues, the main variable used to measure the change in the technology stock, ΔTECH, is R&D/Y, the ratio of the flow of R&D expenditures to value added. As we have noted above we think this is a good measure of technological progress and is the main variable we consider in our empirical work. Some results based on alternative technology measures are also discussed below.

Finally, because yearly variations in industrial R&D intensity tend to be small, one may believe that the estimation of models based on annual industry data is not suitable. As such, the main results that we present specify equation (2) in longer frequency differences (four year changes). Nevertheless the results are robust to using shorter or longer changes and we also report results from annual data. All reported results are based on annualizing the data to ensure comparability across models based on data of different frequencies.

B. Basic Regressions

Table III reports simple regressions of (annualized) four year and one year changes in skilled wage bill and employment shares on R&D intensity (and year dummies). For the four year models, where we have full data these models cover four time periods (1973-77, 1977-81, 1981-85 and 1985-89) and exceptions to this are detailed in the notes to the Table. Because the specifications cover the same industries in different time periods we let the industry-specific errors be correlated over time (in other words we allow for random effects in the differenced specifications). Each equation also incorporates a set of year dummies to control for country-specific common time effects.

In all cases, the estimated coefficients on the R&D variable are positive and are almost always statistically significant at the 5 percent level. Only in 3 cases out of 17 in the four year change models (Sweden, changes in non-production wage bill shares; United Kingdom, changes

in high education employment shares; United States, changes in high education employment shares) is the estimated coefficient on R&D intensity not significant at the 5 percent level and even there the p-values testing the null hypothesis of no association are .15, .07 and .07 respectively. In the one year change models 14 of the 16 of the estimated R&D coefficients are significantly different from zero (and the two that are not - high education employment shares in the United Kingdom and United States - have p-values of .22 and .07 respectively).[11]

The regressions therefore paint a very clear picture about the relationship between skill upgrading and R&D intensity. It is clearly the more R&D intensive industries that have seen faster increases in non-production wage bill and employment shares and high education shares in the seven countries we study. We view the fact that a significant correlation is obtained for 'skill' measures based on non-production and education based shares as very reassuring for interpreting the observed changes as illustrating faster skill upgrading associated with higher industry R&D intensity in these countries.

C. Cost Share Based Models

The results of implementing the more detailed econometric models based on equation (2) are contained in Table IV. The upper panel of the Table reports models analyzing changes in non-production wage bill shares and the lower panel considers changes in non-production employment shares. In each case three specifications are reported. For the non-production wage bill shares, the first two rows contain coefficient estimates from models based on four year changes with the first row imposing constant returns to scale (CRS: $\alpha_j = - \beta_j$ in the context of equation (2)) and the second row relaxing this assumption. The third row reports models based

[11] The same pattern of results is also preserved in longer differenced models. Notice also that the one year models use all the data we have compiled and in some countries this goes up to 1991. As such the coefficients are not strictly comparable (but restricting to the same time period as the four year models produced similar results).

on annual year-on-year changes for the non-CRS case. For the non-production employment share equations the first and second rows consider four year changes with the former excluding the relative wage term and the latter including it (except for Germany where we do not have wage data). The third row (second for Germany) reports employment share models based on the annual data.

Overall, the wage bill share models in the upper panel of Table IV are very much in line with the skill-biased technological change hypothesis as there is evidence of a complementarity between new technology and changes in skilled wage bill shares in all five countries considered. The coefficient on R&D/Y is estimated to be positive across all specifications and is significantly different from zero in almost all cases. We also find a positive correlation between the growth of capital intensity and the skill upgrading in every country except Japan. This is important as it is likely that some of the effect of technology on the labor market occurs through being 'embodied' in more recent vintages of capital goods. What is more, the estimated coefficients are robust to specification of equations in four year changes as compared to looking at annual year-on-year regressions.[12]

Turning next to the lower panel of the table we find broadly supportive results from the employment share equations, with R&D intensity being positively associated with faster growth of the proportion of skilled employees across all six countries. One should note that the parameter estimates in the employment share equations were robust to including relative industry wage

---

[12] Only the non-CRS specifications are reported for the one year change regressions. As for the four year models the same pattern emerged if constant returns were imposed. In Denmark and Japan the estimated coefficients on the R&D variable were smaller when CRS is imposed. By contrast, in Sweden, the United Kingdom and United States the estimated coefficients were larger. The actual coefficient estimates (standard errors) were: Denmark .022 (.014); Japan .037 (.015); Sweden .039 (.012); United Kingdom .024 (.010); United States .018 (.007).

terms - defined as $\log(W^{NP}/W^{P})_{ijt}$ - where the NP and P superscripts stand for non-production and production respectively. This, however, is where the only notable difference between the four year and one year growth models occurred. In the year-on-year regressions the coefficient on the relative wage is fairly precisely estimated and is significantly negative in all countries except Japan. Furthermore, they hint at a stronger (i.e. more negative) wage effects in the United States than elsewhere. This pattern is less clear in the longer differenced models where the wage effects are estimated with much less precision.

Finally, returning to the wage bill share equations, when the relative wage terms were included in the wage bill share specifications their coefficients were estimated to be positive but it should be noted that, since the dependent variable includes wage terms in its definition, the estimated coefficients on the relative wage terms are biased upwards. Despite this, but most important for our focus, the coefficients on the R&D and physical capital terms in Table 4 and were essentially unaffected by the inclusion of the industry specific relative wage terms.[13]

D. Cross-Country Differences in the Size of the Technical Change Effect

To what extent is the effect of R&D similar across countries? Simply looking at the estimated coefficients in Table IV gives the impression that their magnitude differs and, given that skill upgrading has occurred to a different degree across countries, their ability to explain the observed changes varies across countries. The most pertinent observation here is that the R&D coefficients are smallest in the United Kingdom and United States, yet skilled wage bill and employment shares rose fastest in those two countries.

To probe the differences further we pooled the data and tested restricting the R&D

---

[13] For the 5 countries considered (non-CRS specifications) they were as follows (standard errors in brackets): four year changes - Denmark .038 (.015); Japan .056 (.020); Sweden .022 (.008); UK .015 (.011); US .012 (.008); one year changes - Denmark .035 (.010); Japan .044 (.020); Sweden .032 (.007); UK .021 (.012); US .013 (.008).

coefficients to be common across countries. One cannot reject moving from the most general specification (with all variables allowed to have different effects by country) to the restricted model where there is a common R&D coefficient. In the four year change wage bill and employment share models for the five countries with employment and wage data (Denmark, Japan, Sweden, the United Kingdom and United States) pooled data models with a common R&D effect produced coefficients (and associated standard errors) of .021 (.006) in the wage bill share equation and .021 (.007) in the employment share equation. A $\chi^2(4)$ test of constancy of the estimated R&D effect across countries produced a test statistic of 6.96 for wage bill shares and 7.11 for employment shares (5 percent critical value = 9.49).

A more detailed examination of these results, however, revealed that one can identify some country-specific variations around these average effects. In fact, for both wage bills and employment shares, a model that restricts the United Kingdom and United States to have equal R&D effects, Denmark and Japan to have equal effects and lets Sweden have its own R&D effect cannot be restricted to the common R&D coefficient model. In this model the R&D coefficients are smaller in the United Kingdom/United States case at .013 (.006) for wage bill shares and .013 (.007) for employment shares (standard errors in parentheses). In Sweden they are .022 (.013) and .025 (.007) respectively. And they are higher in Denmark/Japan at .048 (.012) and .046 (.012). The appropriate $\chi^2(2)$ test statistics of simplifying to a model with identical R&D effects in all countries can be rejected (with test statistics of 6.38 for wage bill shares and 6.26 for employment shares, 5 percent critical value = 5.99).

The pattern that emerges is therefore an intriguing one. There is a significant association between skill upgrading and R&D intensity in all countries. Put more bluntly, technology matters everywhere. However, in the countries which have experienced bigger increases in wage inequality and faster skill upgrading, a unit increase in R&D intensity is associated with a

significantly lower shift in skill structure. On the other hand, in countries where wage inequality has remained stable and smaller shifts in skill structure our measure of technology can account for a larger fraction of the observed change.

IV. FURTHER CONSIDERATIONS

There are many issues and extensions that follow from the nature of the specifications reported in the previous section. In this section we investigate some of these where we probe further the robustness of the key findings.

A. Computer Usage

A common alternative to R&D based technology measures is some index of computer use across industries. For the United States and United Kingdom the existence of microdata on computer usage means it was possible to calculate the proportion of workers in our industries who were using computers at work in the mid-1980s. This is essentially the same variable used by Autor, Katz and Krueger [1997] and has the advantage of being a direct measure of the diffusion of a new technology. One major disadvantage is that the computer measure is only available for two countries in the mid 1980s.[14] The correlation of computer use with R&D intensity was high (.78 in the United Kingdom and .83 in the United States) and the industry based cross-country correlation is also high at .79. Re-running the cost share based models in Table IV replacing the R&D intensity variable with the computer usage variable gave similar results, uncovering an important complementarity between skill upgrading and this alternative

[14] Data comes from the Current Population Survey in the United States and from the British Social Attitudes Survey in the United Kingdom.

measure of technology.[15]

B. Foreign Competition

The main alternative story to technology driven changes is that increased foreign competition has damaged the position of less skilled workers (Freeman [1995], Wood [1994]). We have constructed two measures of changes in import competition for our industry panels (changes in the ratio of total imports to value added and in the ratio of imports from non-OECD countries to value added) and examined the extent to which one sees a cross-country correlation pattern by industry. At first glance the cross-country patterns of increases in import competition look like they may be broadly supportive of the trade view. Like skill upgrading (and R&D intensity) bigger changes in import competition from 1973-89 seem to be clustered in much the same industries over time. For the 21 pairwise comparisons of cross country correlations that we can carry out with our data, all were positive for both import variables, 7 were significant (at the 5 percent level) for the total imports variable and 17 were significant for the non-OECD imports variable. So it appears to be the case that faster increases in import competition, especially from non-OECD countries, were concentrated in similar industries over time (it is also true that higher levels of import intensity are concentrated in the same industries).

Taking the next step on to see whether these import variables were correlated with the extent of skill upgrading, we then augmented our cost share model with these extra variables. On some readings of the 'trade hypothesis' one would expect the industries with faster rising import intensities to be reducing the proportion of their unskilled workers at a faster rate. Table V tests

---

[15] The estimated coefficients (and associated standard errors) were as follows: United Kingdom - wage bill shares .010 (.004) [1 year changes], .006 (.004) [4 year changes]; employment shares .011 (.003) [1 year changes], .008 (.004) [4 year changes]; United States - wage bill shares .011 (.005) [1 year changes], .011 (.005) [4 year changes]; employment shares .011 (.004) [1 year changes], .010 (.004) [4 year changes].

this hypothesis. To keep things clear only non-CRS specifications in the four year change models are reported (the same pattern of results is upheld in one year models and if constant returns are imposed). Four specifications are reported for each country, the first two rows including the imports variables in levels, the final two incorporating the variable in changes. In no case was the coefficient on the imports variable correctly signed and significantly different from zero. In many cases the imports coefficient attracted a perverse negative sign. Whilst rising import competition is concentrated in similar industries across countries over time, and the same is true of skill upgrading, they do not appear to be the same ones.

What is more, it is important to note that the R&D coefficient remains very robust to the inclusion of the trade variables. Although this robustness is reassuring a cautionary note must be added. Supporters of the trade-based explanation of changing skill structures emphasise that the effects of trade are a general equilibrium phenomenon. Thus one may not necessarily expect there to be a positive correlation between within industry shifts in import intensity and the skill structure. In related work (Desjonqueres, Machin and Van Reenen [1998]) we show that even if one examines disaggregated non-traded sectors it is possible to uncover evidence of skill upgrading - a fact which is very hard to reconcile with a pure trade based explanation.[16]

C. Endogeneity of R&D

In common with most of the existing literature we have so far taken technical change to be exogenous. This may be a problematic assumption. If firms expect skills to be growing at a particularly fast rate in their sector it may be less costly for them to adopt new technologies and perform more R&D. Thus the technology-skills correlation would be due to endogenous

[16] This work also shows: (i) the `price puzzle' of a weak correlation between skill-intensive industry and price changes exists outside the United States; (ii) patterns of skill change in developing countries are largely inconsistent with simple (Heckscher-Ohlin type) trade models.

technological advance (as is suggested by some endogenous growth theories). To the extent that R&D only responds slowly to shocks to skills (e.g. because of high adjustment costs) this may be less of a severe problem (in econometric terms it is not strictly exogenous, but pre-determined).[17]

It is notoriously hard to find convincing instruments for technology. Here we investigate the possibility of using government funded business enterprise R&D. If government behaviour can be taken as exogenous then, although government-funded R&D is likely to affect the amount of R&D conducted in the industry, it will be uncorrelated with the error term in the cost share equation. Government funded R&D varies across industries and over time and we use this independent variation in constructing Instrumental Variable (IV) results. Table VI contains these results. The first row for each country reports the coefficient and standard error on the government R&D variable in the first-stage reduced form 'R&D equation'. As can be seen the instrument is highly significant in all cases. Next consider the second and third rows which present estimates of the IV R&D coefficient in the cost share equations (with and without imposing constant returns). Compared to the models where R&D is assumed exogenous, the IV coefficient estimates, although estimated with less precision, are remarkably close. In some countries (such as Japan) the coefficient actually rises in magnitude, though the main pattern is no change or a small fall. In no case are the coefficients significantly different from the case where R&D is assumed exogenous and the overall thrust of results remains very robust.

[17] A second reason for instrumenting could be measurement error associated with the problem of 'double counting'. This is because few production workers are involved in R&D. However, since the number of R&D workers in an industry is small this is likely to be a second order problem.

D. Spillovers

A further possible criticism of using own R&D as a measure of technology is that it ignores any international spillovers arising from the public good nature of knowledge. Constructing a spillover pool is by no means easy[18], but one simple method is to calculate the amount of worldwide R&D for each industry using the entire STAN database (essentially all OECD R&D). After subtracting own R&D and normalizing on world value added in the industry (net of own value added) the spillover variable was entered alongside the own R&D variable. One should bear in mind that, as with the cross-country R&D correlations considered earlier (in Table II), own R&D and the spillover term are highly correlated so identification of separate effects is asking rather a lot. Nevertheless, the broad pattern that emerged is of some interest. In the United Kingdom and the United States the coefficient on the spillover variable was small and statistically insignificant. But in the other countries, it was estimated to be positive and statistically significant and the coefficient on own R&D was driven to insignificance.[19] Taken as a whole the results suggests spillovers to be potentially more important in the smaller Scandinavian economies and Japan than in the United States and United Kingdom.

---

[18] See Coe and Helpman [1995] for a recent attempt to use trade flows to construct an international spillover measure.

[19] For the non-CRS case, in four year change wage bill share models, the following coefficients (standard errors) were obtained: Denmark, (R&D/Y) .001 (.006), spillover .040 (.006); Japan, (R&D/Y) .008 (.015), spillover .036 (.015); Sweden, (R&D/Y) -.066 (.050), spillover .097 (.050); United Kingdom, (R&D/Y) .018 (.019), spillover -.006 (.021); United States, (R&D/Y) .024 (.015), spillover -.015 (.024). The same pattern of results emerged in the CRS case (insignificant own R&D effects with positive significant spillovers in Denmark, Japan and Sweden), except in the United Kingdom and United States where the positive own R&D effect was larger and more precisely determined (at .042 (.014) and .030 (.016) respectively). The coefficient on the spillover variable remained negative and insignificant in both these countries.

V. CONCLUSIONS

This paper has reported evidence related to the question of whether the observed intertemporal shifts in the skill structure of international labor markets can be accounted for by skill biased technological change. Using a newly constructed industry level database we have contrasted the experience of seven industrialized nations: Denmark, France, Germany, Japan, Sweden, the United Kingdom and the United States. Our countries provide an interesting comparison because, over the time period considered, there was skill upgrading in all cases but there were also dramatic changes in the wage structure of the Anglo-Saxon nations, with relative stability elsewhere. If a similar common technology shock hit the developed world then the contrast between these countries should give some insight into the relative importance of different explanations for changes in the skill structure.

Our analysis leads to the conclusion that there exist important skill-technology complementarities across all countries. This finding was robust to experiments using different measures of skill, introducing trade variables and instrumenting R&D. Thus it is likely that the move towards higher R&D intensities and increased computer usage (see also Autor, Katz and Krueger [1997]) are factors that have contributed to reducing the relative demand for the unskilled.

To what extent can technical change account for changes in the structure of labor markets in industrialized nations? The results presented here can be interpreted as offering evidence that technology has been very important. It seems that R&D intensity pushes up the demand for skills and R&D intensity was higher in all countries in the 1980s than in the 1970s. There are several important caveats to be born in mind, however. First, a full analysis needs to take into account the differential growth in the supply of skilled workers. Although this has been increasing across all countries the rate of acceleration has been different and equilibrium skill differentials will in

part reflect these differences. Secondly, although R&D intensity is relatively high in the Anglo-Saxon nations, the rate of growth has been slower and the estimated coefficients on the R&D variable in skill upgrading equations appear to be somewhat lower in United Kingdom and United States than in other countries. Taken together with the fact that the skill structures were changing most rapidly in these two countries it seems likely that there are other factors in addition to technology that have contributed to the declining labor market position of unskilled workers.

The additional factor that has received most attention to date is rising international trade and it is natural that much current research focuses on this. We, however, remain rather sceptical about the direct role of trade (i.e. through Heckscher-Ohlin type routes). A more fruitful path may well be to better integrate arguments to do with the declining role of labor market institutions into generating a fuller understanding of what lies behind the observed changes in skill structure. The ability of institutions to set wages, affect training and reduce the power of firms to lay off unskilled workers are all likely to impact on relative wages and employment. The cross-country pattern of results reported in this paper, coupled with the dramatic weakening of these institutions in the Anglo-Saxon countries in the 1980s and their relative persistence in Europe, suggests that this could well be an important factor - in addition to technical change - in explaining the changing skill structure of the countries examined here.

DATA APPENDIX

The data used in this paper comes from a variety of industry and individual level data sources. The main aim is to consider the relationship between skill upgrading and technology across countries in the same industries. This requires the matching of data from a number of sources and at different levels of industry disaggregation. We focus on the manufacturing sectors of seven countries (Denmark, France, Germany, Japan, Sweden, the United Kingdom and United States). From our matching of the relevant data sources described below, aggregate manufacturing can be broken down into 16 industries at (broadly) the 2-digit level. All the industry based work in the paper that requires the use of R&D data focusses on 15 industries only, dropping the transport goods sector because of problems with the R&D data for this sector (see below).

The 15 sectors considered were: chemicals (including drugs); electrical, radio, TV & communications; food, beverages & tobacco; iron & steel; metal products; non-electrical machinery (including computers); non-ferrous metals; non-metallic mineral products; other manufacturing; paper products & printing; coal & petroleum products; professional goods; rubber and plastic goods; textiles, apparel & leather; wood products & furniture.

The data sources used to set up the panel data for these industries over time were the following:

1. OECD STAN Database

STAN is a dataset constructed in a long-term project by the OECD who work together with the Central Statistical Offices of OECD countries to compile consistent industry level data over time from the early 1970s. All data are originally in unscaled national currencies. They can be converted to dollars using annual average values of the exchange rate. Industrial classifications are detailed in OECD [1997c]. There are three OECD databases which can be merged consistently in the STAN series:

(a) Business Enterprise R&D (ANBERD). This contains data on R&D conducted by industry regardless of funding source and is available from 1973 for the following countries: UK, France, Canada, Germany, Italy, Japan, the US, Australia, Denmark, Finland, the Netherlands and Sweden for 22 disaggregated industries (see OECD [1997b]). These figures have been adjusted to ensure comparability and so differ from the official figures for the individual countries. State owned industries' R&D are included in all countries. As noted above there appeared to be problems in constructing the R&D figure for the transport industries (this is related to the large amount of military/government expenditure, especially in the United Kingdom and United States, erratic figures for the aerospace industries and the fact that R&D data was missing for some sub-sectors of the transport industry). Consequently this industry was dropped.

(b) OECD, DSTI(STAN/Industrial Database) contains data on investment, value added and exchange rates. From the investment data capital stock measures were constructed using the perpetual inventory method and a depreciation rate of 8.4% (a weighted average of the depreciation rates for plant and machinery and buildings used in OECD [1991]). Initial year stocks assumed a pre-sample growth rate of 5%. Production used is National Accounts compatible production (gross output) in current prices. This means that data is National Accounts compatible where available, otherwise OECD estimates are made.

(c) Import and export data are from OECD's Compatible Trade and Production database (COMTAP). Figures are consistent across countries but may not be strictly comparable to trade flows published in other sources.

2. United Nations General Industrial Statistics Database (UNISD)

Data for wage bills and employment for production/non-production workers were obtained for Denmark, Sweden, the United Kingdom and United States from the Statistical Division of the United Nations from 1970 onwards (up to 1991 in some countries). The key data is reported in terms of "employees" and "operatives", the latter of which are taken to be production workers and non-production workers are the rest. More recent data is not available as the UN stopped collecting data disaggregated in this way after responsibility for the UNISD was moved from New York to Vienna. The UNISD database contains similar information (in particular on capital formation) to the STAN database, but differs from it in that the STAN database is derived from sample information which is then calibrated by national accounts numbers, whereas the UN figures report the survey results (e.g. from the United States Annual Survey of Manufactures or the United Kingdom Census of Production). After cleaning the data consistently defined data on non-production shares were available for 1973-89 (Denmark) and 1970-85 (Sweden), 1970-90 (United Kingdom) and 1970-91 (United States).

3. OECD Bilateral Trade Database

Data on imports from non-OECD countries were matched in from the OECD Bilateral Trade Database.

4. OECD OFBERD

OFBERD ('Official' BERD) is an unpublished dataset compatible with STAN/ANBERD which is compiled by the OECD. In OFBERD R&D performed by the business sector is broken down into sources of finance. We distinguish between R&D funded by government and by the private sector (domestic or foreign). Government funded R&D is primarily direct grants and contracts.

5. Individual-Level Data Sources

Individual-level data sources were aggregated to the industry level defined above for the following:
(a) Non-production wage bill and employment shares in Japan (Source: Japanese Wage Survey) and non-production employment shares in Germany (Source: Mikrozensus). As data was not available for all years some values were imputed (Japan for 1973 and where data points were missing in other years).
(b) High education employment shares (defined as the share of the workforce with a college degree) for France (1977-91, Source: Enquete Emploi), Germany (1977-91, Source: Mikrozensus), Japan (1977-90, Source: Japanese Wage Survey), Sweden (1986 and 1993, provided by Par Hansson), the United Kingdom (1977-91, Source: Labour Force Survey) and the United States (1977-91, Source: Current Population Survey). In some cases data was not available annually so in these cases data was interpolated between years and in Sweden only two years were available (1986 and 1993).

FIGURE I: CHANGES IN NON-PRODUCTION WAGE BILL AND EMPLOYMENT SHARES AND HIGH EDUCATION EMPLOYMENT SHARES - WITHIN AND BETWEEN COMPONENTS OF ANNUALIZED CHANGES

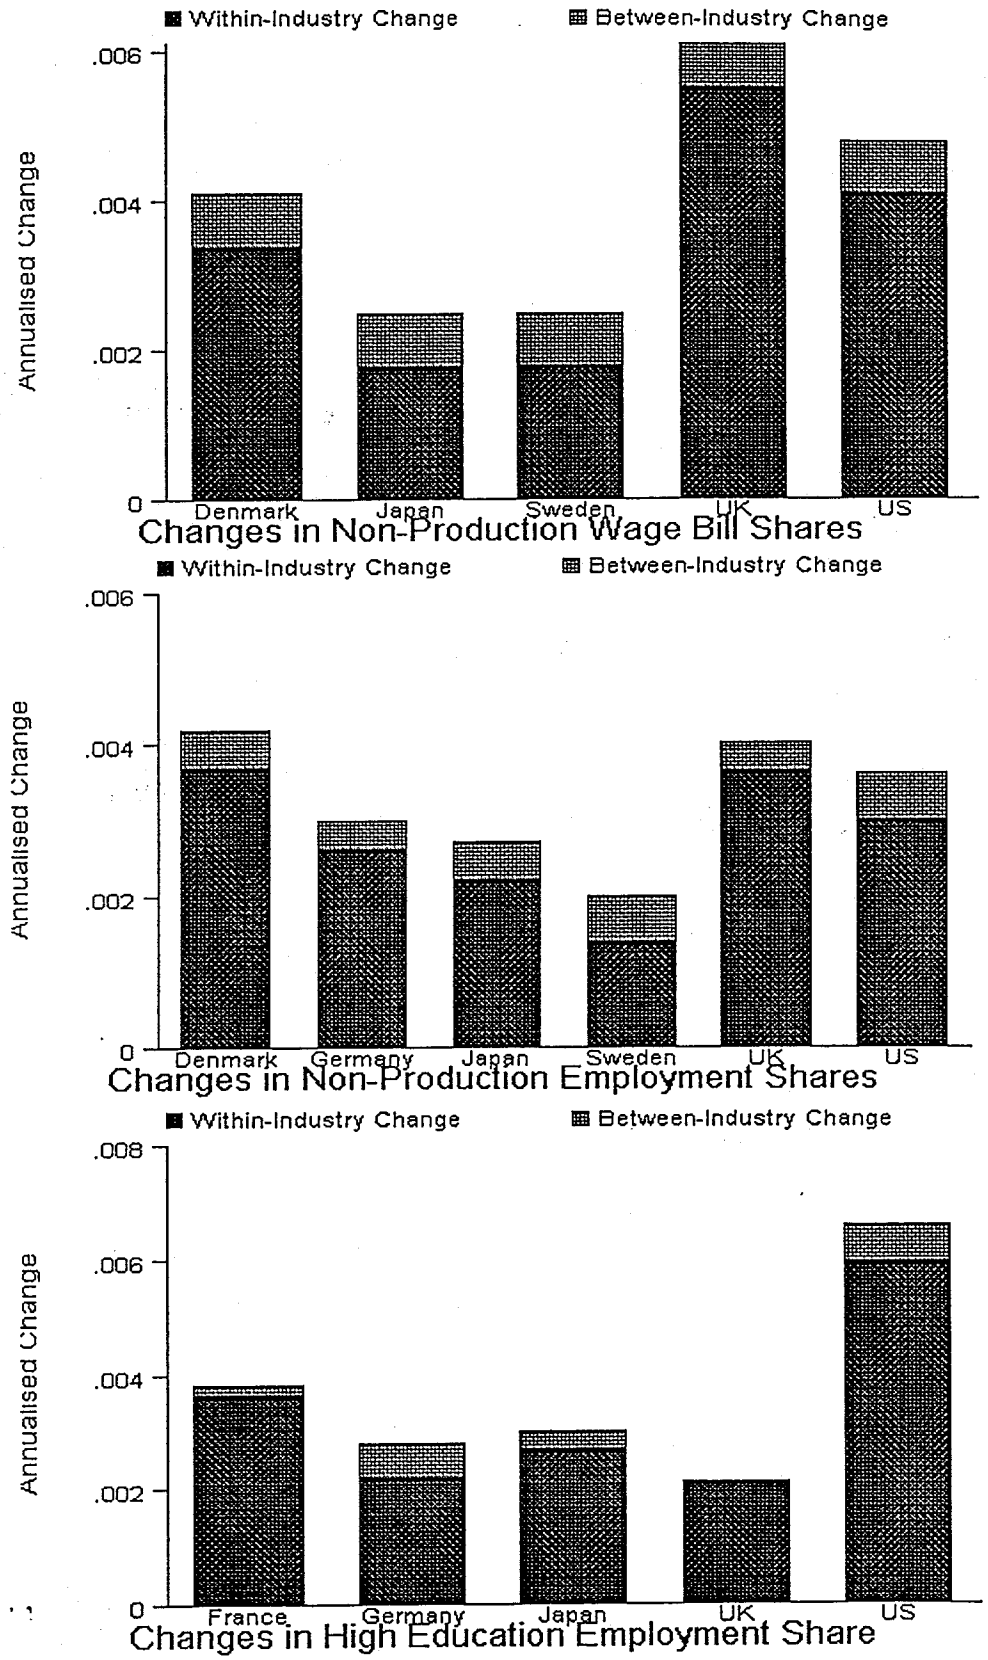

TABLE I: NON-PRODUCTION WAGE BILL AND EMPLOYMENT SHARES, RELATIVE WAGE DIFFERENTIALS, HIGH EDUCATION EMPLOYMENT SHARES AND R&D INTENSITY IN MANUFACTURING

	1973	1977	1981	1985	1989
			Non-Production Wage Bill Shares		
Denmark	.336	.338	.359	.373	.402
Japan	.406 (1974)	.415	.428	.433	-
Sweden	.356	.385	.395	.395	.396
UK	.317	.333	.377	.392	.414
US	.337	.351	.379	.406	.414
			Non-Production Employment Shares		
Denmark	.251	.270	.292	.293	.318
Germany	-	.292	.306	.318	.327
Japan	.339 (1974)	.350	.364	.382	-
Sweden	.271	.288	.299	.304	.303
UK	.260	.278	.311	.321	.325
US	.246	.261	.285	.305	.303
			Non-Production/Production Wage Differentials		
Denmark	1.511	1.382	1.359	1.434	1.437
Japan	1.331 (1974)	1.314	1.310	1.308	-
Sweden	1.487	1.549	1.532	1.493	1.509
UK	1.316	1.292	1.340	1.366	1.470
US	1.553	1.531	1.532	1.559	1.623
			High Education Employment Shares		
France	-	.047	.057	.081	.093
Germany	-	.032	.044	.054	.066
Japan	-	.098	.111	.129	.135
UK	-	.039	.054	.065	.064
US	-	.088	.126	.161	.167
			R&D Intensity (R&D/Value Added)		
Denmark	.021	.022	.027	.031	.039
France	.035	.037	.046	.056	.060
Germany	.032	.037	.043	.052	.055
Japan	.031	.036	.046	.060	.070
Sweden	.038	.050	.063	.080	.081
UK	.043	.046	.064	.062	.060
US	.063	.062	.077	.097	.087

Notes: Non production wage bills, employment and wages are taken from UNISD or from country specific micro data (Germany - Mikrozensus; Japan - Wage Census); R&D intensity is drawn from ANBERD and STAN; high education shares from micro data sources in each country (France - Enquete Emploi; Germany - Mikrozensus; Japan - Wage Census; UK - Labour Force Survey; US - Current Population Survey). For more details see the Data Appendix. High education employment shares are also available for Sweden in two different years (1986 and 1993). Means are .090 in 1986 and .154 in 1993.

TABLE II: CROSS-COUNTRY CORRELATIONS IN INDUSTRY R&D INTENSITY (15 MANUFACTURING INDUSTRIES, 1973-89 AVERAGES, WEIGHTED BY CROSS-COUNTRY MEAN INDUSTRY VALUE ADDED SHARES)

	Cross-Country Correlations of Industry (R&D/Y)					
	Denmark	France	Germany	Japan	Sweden	UK
France	.68*					
	(.01)					
Germany	.79*	.97*				
	(.00)	(.00)				
Japan	.66*	.95*	.97*			
	(.01)	(.00)	(.00)			
Sweden	.73*	.97*	.97*	.96*		
	(.00)	(.00)	(.00)	(.00)		
UK	.73*	.98*	.95*	.92*	.98*	
	(.00)	(.00)	(.00)	(.00)	(.00)	
US	.68*	.90*	.85*	.91*	.93*	.94*
	(.01)	(.00)	(.00)	(.00)	(.00)	(.00)

Notes: These are pairwise correlation coefficients based on 15 manufacturing industries (except for correlations for Denmark which are based on 14 industries due to missing data on the petroleum industry). They are weighted by the pairwise cross-country mean industry value added share in total value added. P-values testing the null of independence in parentheses (* denotes significance at .05 level or better).

TABLE III: BASIC REGRESSIONS OF CHANGES IN SKILL UPGRADING ON R&D INTENSITY - FOUR YEAR CHANGES (ANNUALIZED) AND ONE YEAR CHANGES

			Changes in Non-Production Wage Bill Share	Changes in Non-Production Employment Share	Changes in High Education Employment Share
Denmark	Four Year Changes	Coefficient (standard error) on R&D/Y	.028 (.013)	.031 (.012)	
		Sample size	56	56	
	One Year Changes	Coefficient (standard error) on R&D/Y	.024 (.011)	.021 (.009)	
		Sample size	173	173	
France	Four Year Changes	Coefficient (standard error) on R&D/Y			.052 (.008)
		Sample size			42
	One Year Changes	Coefficient (standard error) on R&D/Y			.047 (.003)
		Sample size			196
Germany	Four Year Changes	Coefficient (standard error) on R&D/Y		.021 (.007)	.026 (.007)
		Sample size		45	39
	One Year Changes	Coefficient (standard error) on R&D/Y		.024 (.007)	.022 (.007)
		Sample size		210	186
Japan	Four Year Changes	Coefficient (standard error) on R&D/Y	.050 (.016)	.043 (.017)	.019 (.008)
		Sample size	45	45	45
	One Year Changes	Coefficient (standard error) on R&D/Y	.037 (.016)	.033 (.015)	.020 (.008)
		Sample size	172	172	189
Sweden	Four Year Changes	Coefficient (standard error) on R&D/Y	.013 (.009)	.020 (.008)	.032 (.007)
		Sample size	45	45	15
	One Year Changes	Coefficient (standard error) on R&D/Y	.036 (.011)	.038 (.009)	
		Sample size	157	157	
UK	Four Year Changes	Coefficient (standard error) on R&D/Y	.024 (.009)	.025 (.009)	.013 (.007)
		Sample size	60	60	60
	One Year Changes	Coefficient (standard error) on R&D/Y	.026 (.009)	.026 (.009)	.011 (.009)
		Sample size	255	255	210
US	Four Year Changes	Coefficient (standard error) on R&D/Y	.024 (.007)	.020 (.007)	.025 (.014)
		Sample size	60	60	60
	One Year Changes	Coefficient (standard error) on R&D/Y	.021 (.007)	.022 (.007)	.020 (.011)
		Sample size	270	270	210

Notes: Nonproduction shares: four year changes based on 15 industry manufacturing panel data for four time periods (1973-77, 1977-81, 1981-85, 1985-89) for all countries except Germany (1977-81, 1981-85, 1985-89), and Japan and Sweden (1973-77, 1977-81, 1981-85). Full sample sizes are 60 but may be less due to data problems in some industries and years. Education shares: four year changes based on 15 industry manufacturing panel data for three time periods (1977-81, 1981-85, 1985-89) except for Sweden (1986-93). One year change models use data on all available years. All four year changes are annualized and all regressions include a full set of time dummies. Regressions are weighted by industry size (wage bill share or employment share). Estimation is by GLS/random effects where the industry errors are allowed to be correlated for industries over time. Heteroskedasticity consistent standard errors in parentheses.

TABLE IV: CHANGE IN NON-PRODUCTION WAGE BILL AND EMPLOYMENT SHARE EQUATIONS IN MANUFACTURING

Changes in Non-Production Wage Bill Shares

			(R&D/Y)	Δlog(K/Y)	Δlog(K)	Δlog(Y)	Sample size	Test of CRS (χ^2)
Denmark	Four Year Changes	CRS	.027 (.013)	.042 (.017)			54	
		Relax CRS	.039 (.015)		.025 (.017)	-.079 (.019)	54	8.34 (p = .00)
	One Year Changes	Relax CRS	.037 (.011)		.035 (.014)	-.098 (.016)	173	17.25 (p = .00)
Japan	Four Year Changes	CRS	.050 (.014)	-.035 (.011)			45	
		Relax CRS	.056 (.020)		-.043 (.016)	.031 (.012)	45	.43 (p = .51)
	One Year Changes	Relax CRS	.047 (.021)		-.019 (.022)	.000 (.016)	172	.39 (p = .53)
Sweden	Four Year Changes	CRS	.039 (.014)	.037 (.017)			39	
		Relax CRS	.020 (.014)		.083 (.024)	-.008 (.022)	39	9.04 (p = .00)
	One Year Changes	Relax CRS	.033 (.012)		.041 (.021)	-.013 (.008)	157	1.83 (p = .18)
UK	Four Year Changes	CRS	.024 (.010)	.014 (.022)			60	
		Relax CRS	.013 (.008)		.051 (.022)	.038 (.021)	60	9.99 (p = .00)
	One Year Changes	Relax CRS	.019 (.011)		.046 (.022)	-.011 (.005)	255	2.34 (p = .13)
US	Four Year Changes	CRS	.021 (.007)	.030 (.018)			60	
		Relax CRS	.013 (.008)		.064 (.020)	-.014 (.015)	60	13.16 (p = .00)
	One Year Changes	Relax CRS	.013 (.008)		.070 (.019)	-.039 (.011)	270	3.59 (p = .06)

Changes in Non-Production Employment Shares

			(R&D/Y)	Δlog(K)	Δlog(Y)	Δlog(W^{NP}/W^{P})	Sample size
Denmark	Four Year Changes	Exclude relative wage	.040 (.015)	.019 (.020)	-.061 (.021)		54
		Include relative wage	.040 (.015)	.022 (.016)	-.068 (.017)	-.141 (.027)	54
	One Year Changes	Include relative wage	.034 (.010)	.027 (.013)	-.074 (.012)	-.115 (.026)	173
Germany	Four Year Changes	Exclude relative wage	.026 (.006)	-.021 (.013)	.000 (.007)		45
	One Year Changes	Exclude relative wage	.029 (.007)	-.030 (.013)	-.002 (.003)		210
Japan	Four Year Changes	Exclude relative wage	.046 (.015)	-.045 (.021)	.044 (.011)		45
		Include relative wage	.047 (.015)	-.045 (.021)	.044 (.013)	-.008 (.017)	45
	One Year Changes	Include relative wage	.047 (.020)	-.029 (.026)	.002 (.016)	.023 (.020)	172

		Include relative wage	.024 (.007)	.056 (.012)	-.002 (.014)	-.034 (.078)	39
	One Year Changes	Include relative wage	.034 (.006)	.035 (.016)	-.007 (.007)	-.074 (.020)	157
UK	Four Year Changes	Exclude relative wage	.016 (.010)	.026 (.019)	.040 (.018)		60
		Include relative wage	.015 (.010)	.033 (.021)	.040 (.019)	-.063 (.079)	60
	One Year Changes	Include relative wage	.021 (.011)	.028 (.018)	-.003 (.006)	-.088 (.031)	255
US	Four Year Changes	Exclude relative wage	.010 (.008)	.059 (.016)	-.011 (.011)		60
		Include relative wage	.012 (.008)	.061 (.017)	-.012 (.013)	-.124 (.088)	60
	One Year Changes	Include relative wage	.013 (.008)	.073 (.020)	-.038 (.011)	-.203 (.021)	270

Notes: Four year changes based on 15 industry manufacturing panel data for four time periods (1973-77, 1977-81, 1981-85, 1985-89) for all countries except Germany (1977-81, 1981-85, 1985-89), and Japan and Sweden (1973-77, 1977-81, 1981-85). Full sample sizes are 60 but may be less due to data problems in some industries and years. One year change models use data on all available years. All four year changes are annualized and all regressions include a full set of time dummies. Regressions are weighted by industry size (wage bill share or employment share). Estimation is by GLS/random effects where the industry errors are allowed to be correlated for industries over time. Heteroskedasticity consistent standard errors in parentheses.

TABLE V: WAGE BILL SHARE EQUATIONS INCLUDING IMPORTS VARIABLES (FOUR YEAR CHANGES)

	Changes in Non-Production Wage Bill Shares (Four Year Change, Annualized)						
	Definition of I	I/Y	Δ(I/Y)	(R&D/Y)	Δlog(K)	Δlog(Y)	Sample size
Denmark	All Imports	-.000 (.000)		.040 (.016)	.024 (.017)	-.079 (.020)	54
	Non-OECD Imports	-.004 (.003)		.043 (.018)	.020 (.018)	-.079 (.021)	54
	All Imports		-.002 (.009)	.039 (.015)	.025 (.017)	-.080 (.021)	54
	Non-OECD Imports		.002 (.012)	.039 (.016)	.024 (.017)	-.079 (.019)	54
Japan	All Imports	-.001 (.002)		.056 (.019)	-.044 (.016)	.031 (.012)	45
	Non-OECD Imports	-.002 (.003)		.059 (.019)	-.049 (.017)	.032 (.012)	45
	All Imports		.005 (.036)	.055 (.020)	-.043 (.016)	.032 (.015)	45
	Non-OECD Imports		.007 (.034)	.055 (.020)	-.043 (.016)	.032 (.015)	45
Sweden	All Imports	.001 (.001)		.013 (.019)	.088 (.025)	-.005 (.025)	39
	Non-OECD Imports	-.002 (.002)		.027 (.010)	.082 (.025)	-.014 (.021)	39
	All Imports		.001 (.007)	.020 (.015)	.083 (.023)	-.007 (.030)	39
	Non-OECD Imports		.006 (.018)	.020 (.015)	.084 (.024)	-.006 (.027)	39
UK	All Imports	.001 (.001)		.012 (.009)	.052 (.023)	.041 (.022)	60
	Non-OECD Imports	.002 (.003)		.013 (.009)	.052 (.022)	.041 (.023)	60
	All Imports		-.019 (.009)	.017 (.009)	.053 (.021)	.023 (.022)	60
	Non-OECD Imports		-.014 (.015)	.013 (.009)	.052 (.023)	.036 (.021)	60
US	All Imports	-.003 (.002)		.017 (.008)	.059 (.018)	-.016 (.016)	60
	Non-OECD Imports	-.004 (.003)		.016 (.008)	.058 (.020)	-.013 (.015)	60
	All Imports		-.002 (.022)	.014 (.008)	.064 (.021)	-.015 (.018)	60
	Non-OECD Imports		-.040 (.032)	.015 (.007)	.065 (.019)	-.019 (.016)	60

Notes: Imports data is taken from OECD STAN and Bilateral Trade databases. All equations include the same variables as the non-CRS specifications in Table IV. All four year changes are annualized and all regressions include a full set of time dummies. Regressions are weighted by industry size (wage bill share or employment share). Estimation is by GLS/random effects where the industry errors are allowed to be correlated for industries over time. Heteroskedasticity consistent standard errors in parentheses.

TABLE VI: INSTRUMENTAL VARIABLE ESTIMATES

Changes in Non-Production Wage Bill Shares (Four Year Changes, Annualized)			
		(R&D/Y)	(Government R&D/Y)
Denmark	R&D Equation		8.625 (1.271)
	Wage Bill Share Equation, CRS: IV Estimates	.016 (.012)	
	Wage Bill Share Equation, Relax CRS: IV Estimates	.022 (.017)	
Japan	R&D Equation		30.193 (11.951)
	Wage Bill Share Equation, CRS: IV Estimates	.059 (.029)	
	Wage Bill Share Equation, Relax CRS: IV Estimates	.070 (.030)	
Sweden	R&D Equation		11.263 (2.427)
	Wage Bill Share Equation, CRS: IV Estimates	.031 (.028)	
	Wage Bill Share Equation, Relax CRS: IV Estimates	.030 (.024)	
UK	R&D Equation		2.218 (.217)
	Wage Bill Share Equation, CRS: IV Estimates	.024 (.010)	
	Wage Bill Share Equation, Relax CRS: IV Estimates	.009 (.010)	
US	R&D Equation		1.964 (.206)
	Wage Bill Share Equation, CRS: IV Estimates	.021 (.010)	
	Wage Bill Share Equation, Relax CRS: IV Estimates	.013 (.009)	

Notes: Government funded R&D estimated from OFBERD dataset. R&D instrumentation equation and wage bill share equations include the same variables as the CRS and non-CRS specifications in Table IV. All four year changes are annualized and all regressions include a full set of time dummies. Regressions are weighted by industry size (wage bill share or employment share). Estimation is by (IV) GLS/random effects where the industry errors are allowed to be correlated for industries over time. Heteroskedasticity consistent standard errors in parentheses.
