

Reported Incomes and Marginal Tax Rates, 1960-2000: Evidence and Policy Implications

Emmanuel Saez, UC Berkeley and NBER*

December 11, 2003

Abstract

This paper uses income tax return data from 1960 to 2000 to analyze the link between reported incomes and marginal tax rates. Only the top 1% incomes show evidence of behavioral responses to taxation. The data displays striking heterogeneity in the size of responses to tax changes over time, with no response either short-term or long-term for the very large Kennedy top rate cuts in the early 1960s, and striking evidence of responses, at least in the short-term, to the tax changes since the 1980s. The 1980s tax cuts generated a surge in business income reported by high income individual taxpayers due to a shift away from the corporate sector, and the disappearance of business losses for tax avoidance. The Tax Reform Act of 1986 and the recent 1993 tax increase generated large short-term responses of wages and salaries reported by top income earners, most likely due to re-timing in compensation to take advantage of the tax changes. However, it is unlikely that the extraordinary trend upward of the shares of total wages accruing to top wage income earners, which started in the 1970s and accelerated in the 1980s and especially the late 1990s, can be explained solely by the evolution of marginal tax rates.

*Emmanuel Saez, University of California, Department of Economics, 549 Evans Hall #3880, Berkeley, CA 94720, saez@econ.berkeley.edu. I am very grateful to Dan Feenberg for his help using the micro tax return data and the TAXSIM calculator. I thank Alan Auerbach, Gerald Auten, Robert Carroll, Dan Feenberg, Martin Feldstein, Wojciech Kopczuk, Andrew Leigh, Thomas Piketty, James Poterba, and especially Joel Slemrod for very helpful comments and discussions. Financial support from the Sloan Foundation and NSF Grant SES-0134946 is gratefully acknowledged.

1 Introduction

Over the last 40 years, the U.S. federal income has undergone very large changes. Perhaps the most striking change has been the dramatic decrease in top marginal income tax rates. From 1950 to the early 1960s, the statutory top marginal income tax rate was 91%. This top rate was reduced to 70% by the Kennedy tax cuts in the mid 1960s. During the Reagan administrations of the 1980s, the top tax rate was further reduced to 50% in 1982 by the Economic and Recovery Tax Act (ERTA) of 1981, and down to 28% in 1988 by the Tax Reform Act (TRA) of 1986. The top tax rate was then increased to 31% in 1991, and further to 39.6% in 1993 by the Omnibus Budget Reconciliation Act (OBRA) of 1993. The top rate has been changed by the 2001 tax reform, it is currently 38.6% (year 2003) and is scheduled to decline to 35% by 2006. While only about five hundred taxpayers were subject to the top marginal tax rate of 91% in the early 1960s, by 2000, more than half a million taxpayers are subject to the top rate.¹ Thus, the continuous and drastic progressivity of the federal income tax system up to the very highest income taxpayers has been replaced by a much flatter tax structure where an upper middle class family can face the same marginal tax rate as the highest income earners in the United States.

In addition to the redistributive effects, the dramatic reductions in top tax rates might have generated large behavioral responses: the net-of-tax value of an additional dollar of pre-tax income (excluding state and local taxes) for those in the highest bracket has experienced enormous variations over the period, from less than 10 cents in the early 1960s to more than 70 cents by the late 1980s, and around 60 cents by 2000. It is plausible to think that such variations might have had substantial effects on the economic activity of high-income earners such as labor supply decisions, career choices, and savings decisions, as well as on the form of compensation (salary versus untaxed fringe benefits for example). Indeed, the intellectual weight behind the dramatic reduction in marginal tax rates in the 1980s was the logic of supply side economics arguing that lower tax rates could generate important increases in economic activity, and perhaps even tax revenues. As documented by Feenberg and Poterba (1993, 2000) and Piketty and Saez (2003), there has indeed been an extraordinary increase in the share of total income accruing to upper groups in the income distribution over the last 25 years. For example,

¹The statistics on the number of taxpayers in each tax bracket have been reported in the Internal Revenue Service (IRS) annual publication *Statistics of Income* regularly since 1961.

the income share of the top 1% taxpayers (excluding capital gains from the analysis), has surged from less than 8% in the early 1970s to almost 17% in 2000 (Piketty and Saez, 2003). Feenberg and Poterba (1993) pointed out that the timing of the increase in top income shares, and most notably the surge in top income from 1986 to 1988 around TRA of 1986, appears to be closely related to the cuts in top tax rates. Slemrod and Bakija (2000) and Piketty and Saez (2003) note, however, that the surge in top incomes accelerated in the late 1990s, although top income tax rates increased substantially in 1993.

The goal of the present paper is to understand the effects of marginal income tax rates on reported incomes by analyzing the shares and composition of incomes accruing to various groups in the top tail of the income distribution, and the marginal income tax rates faced by those groups. The analysis will focus on the 1960-2000 period because this period spans all the important tax changes since World War II,² and allows us to use the large and stratified public-use tax return micro-files released by the IRS since 1960 as well as the TAXSIM tax calculator created and maintained by the NBER to estimate marginal and average tax rates.³

There is a large literature trying to estimate the effects of taxes on such decisions as labor supply, savings, and retirement decisions. Over the past decade, a new literature has emerged which has pointed out that these standard behavioral responses are only components of what drives reported incomes; other responses such as the form of compensation, tax-deductible activities, unmeasured effort, and compliance also ultimately determine reported incomes, and these may be more elastic with respect to taxation. Feldstein (1999) shows that, under certain conditions, it is the overall elasticity of taxable income with respect to the net-of-tax rate (one minus the marginal tax rate) that is relevant for assessing the implications of tax changes for revenue raising and welfare. The influential studies of Lindsey (1987) and Feldstein (1995), examining the 1980s tax cuts, estimated very large elasticities, in excess of one. This striking conclusion has generated a substantial body of work on this central elasticity parameter and generated a wide range of estimated elasticities, ranging from Feldstein and Lindsey's estimates at the high end to close to zero at the low end,⁴ depending on the estimation methodology and

²There are few studies on behavioral responses to taxation in the United States in the pre-war era. Goolsbee (1999) provides a simple analysis of the most important episodes.

³See Feenberg and Coutts (1993) for a description of the TAXSIM calculator.

⁴See Gruber and Saez (2002) for a survey.

the tax reforms considered.

It is important to note that, in contrast to most previous studies, our analysis focuses on reported incomes before deductions such as adjustments to gross income, personal exemptions, standard and itemized deductions. Therefore, our income concept is market income rather than taxable income. As taxable income is a smaller base than gross income and as some components of deductions such as charitable giving or mortgage interest deductions are also responsive to marginal tax rates, the elasticities of taxable income are likely to be larger than the elasticities of reported incomes that we analyze here.⁵

Our analysis shows that only the reported incomes of taxpayers within the top 1% of the income distribution appear to be responsive to changes in tax rates over the 1960-2000 period. Even upper middle income class taxpayers (within the top decile but below the top 1%), which experienced substantial changes in marginal tax rates, show no evidence of responses to taxation, either in the short-run or the long-run. Attributing all the gains of the top 1% relative to the average to the changes in tax rates produces very large elasticities of income with respect to net-of-tax rates, in excess of one. However, allowing for simple secular and non-tax related time trends in the top income share reduces the elasticity drastically (to about 0.5). Top income shares within the top 1% show striking evidence of large and immediate responses to the tax cuts of the 1980s, and the size of those responses is largest for the very top income groups. In contrast, top incomes display no evidence of short or long-term response to the extremely large changes in the net-of-tax rates following the Kennedy tax cuts in the early 1960s.

Data on the composition of income show that part of the response to the 1980s tax cuts has been due to a sudden and permanent shift of corporate income toward the individual income sector using partnerships and subchapter S corporations, legal entities taxed only at the individual level. However, most of the surge in top incomes since the 1970s has been due to a smooth and extraordinary increase in the wages and salary component (which includes stock-option exercises). This wage income surge started slowly in the early 1970s and has accelerated over

⁵Gruber and Saez (2002) find indeed larger elasticities for taxable income than for Adjusted Gross Income. We focus on gross income because the nature and size of deductions has changed considerably over time so that, in contrast to gross income, it is not possible to construct consistent time series of “taxable income”. An extensive literature has analyzed the response of the main components of itemized deductions such as charitable contributions and interest deductions.

the period, and especially during the last decade, and does not seem to be closely related to the timing of the tax cuts. There is evidence of short-term responses of the wage income component around TRA 1986 and OBRA 1993: top wages shares spike just after the tax reduction of 1986 and just before the tax increase of 1993, suggesting that highly paid employees were able to re-time their compensation to take advantage of the tax changes. It is, however, very difficult to tell apart a long term effect of tax cuts from a non-tax related secular widening of the disparity of earnings.

The paper proceeds as follows. Section 2 describes the key identification issues in estimating behavioral elasticities of income with respect to marginal tax rates and shows how such elasticity estimates can be used for tax policy analysis. Section 3 presents the results on income shares and marginal tax rates, as well as the evolution of the composition of top incomes. Section 4 concludes by contrasting the U.S. experience with evidence from other countries.

2 Conceptual Framework and Methodology

2.1 Estimating Elasticities

The economic model underlying the estimation of behavioral responses to income taxation is a simple extension of the static labor supply model. Individuals maximize a utility function $u(c, z)$ increasing in after tax income c (available for example for consumption) and decreasing in before tax income z (earning income is costly for example). The budget constraint takes the form $c = (1 - \tau)z + R$ where τ is the marginal tax rate and R is virtual income. Such maximization generates an individual “reported income” function $z(1 - \tau, R)$ which depends on the net-of-tax rate $1 - \tau$ and virtual income R .⁶ Each individual has a particular income supply function reflecting his skills, taste for labor, etc. Income effects are assumed away so that the income function z is independent of R and depends only on the net-of-tax rate.⁷ The key point is that, in contrast to the standard labor supply model, not only changes in hours of work can

⁶This reported income supply function remains valid in the case of non-linear tax schedules, $c = (1 - \tau)z + R$ then represents the linearized budget constraint at the utility maximizing point.

⁷Labor supply studies in general estimate modest income effects (see Blundell and Pencavel, 1999 for a survey). Gruber and Saez (2002) try to estimate both income and substitution effects in the case of reported incomes, and find very small and insignificant income effects.

affect earnings z but also intensity of work on the job, career choices, form of compensation, tax-deductible activities, etc. The analysis below will show that it is indeed the full response of reported incomes that is relevant for tax policy (a point made by Feldstein, 1999).

The literature on behavioral responses to taxation has attempted to use tax reforms to identify the elasticity of reported incomes with respect to the net-of-tax rate defined as, $e = [(1 - \tau)/z]\partial z/\partial(1 - \tau)$ in the notation used above. In order to isolate the effects of the net-of-tax rate, one would want to compare observed reported incomes after the tax rate change to the incomes that would have been reported had the tax change not taken place. Obviously, the latter are not observed and must be estimated. The simplest method consists in using as proxy reported incomes before the reform and hence relate changes in reported incomes before and after the reform to changes in tax rates.

Lindsey (1987) and Feldstein (1995) applied this methodology to the ERTA 1981 and TRA 1986 tax changes and found that top income groups, which experienced the largest marginal tax cuts, also experienced the largest gains in reported incomes. As a result, Lindsey (1987) and Feldstein (1995) obtain very large elasticities, between 1 and 3, with preferred estimates around 1.5. There are several important issues with those estimates.

First, as pointed out by Slemrod (1996,1998) and Goolsbee (2000b), those elasticities will be upward biased if, for non-tax related reasons, top incomes were increasing more rapidly than average incomes during that period. A large body of work has suggested that non-tax factors, such as skill biased technical progress, the development of international trade, or the decline of unions might have lead to a substantial increase in earnings disparity in the 1980s (see Katz and Autor, 1999 for a survey). To overcome this issue, it would be preferable to compare taxpayers with similar incomes rather than comparing high incomes to middle incomes. In the case of income taxation, this is difficult for two reasons. First, for most reforms, taxpayers with similar incomes face very similar tax changes.⁸ Second, although the discontinuity in marginal tax rates due to the progressive bracket structure creates sharp changes in marginal incentives for taxpayers with very similar incomes,⁹ this cannot be satisfactorily exploited to estimate

⁸In contrast, redistributive programs such as the Earned Income Tax Credit which is targeted to taxpayers with children, allows to use taxpayers with no children but similar income as a plausibly better control group to identify the effects of the program (see, e.g., Eissa and Liebman, 1996).

⁹Saez (2003) tries to exploit this feature and the 'bracket creep' from 1979 to 1981 to identify behavioral

elasticities because it appears that taxpayers either control imperfectly their incomes or are not well aware of the details of the tax code and their precise location on the tax schedule.¹⁰ Therefore, it is conceivable that only large or salient tax changes are likely to generate behavioral responses, raising some interesting and complicated issues about the estimation of behavioral responses and the design of tax policy (see Liebman and Zeckhauser (2003) for an analysis along those lines).

Second, comparing years just before and just after the reform might reveal a short-term elasticity, which can be quite different from the long-term elasticity, which is the relevant parameter for tax policy. Slemrod (1995) discusses this point and Goolsbee (2000a) shows convincingly that executives exercised massively stock options in 1992 in order to avoid the higher tax rate starting in 1993, creating a large short-term elasticity of reported income around OBRA 1993; the longer term elasticity was much smaller and possibly equal to zero.¹¹ Looking at times series spanning a number of years before and after the reform, as in Poterba and Feenberg (1993), can be helpful to make progress on those two issues. Slemrod (1996) proposes an aggregate time-series regression framework, for the period 1954 to 1990, to try and disentangle tax and non-tax influences on the share and composition of income accruing to the top .5% taxpayers.

Third, the Lindsey and Feldstein studies assume implicitly that reported income elasticities are the same for all income groups and, as we will see, the data strongly suggests that those taxpayers with very high incomes are much more responsive to taxation than taxpayers in the middle or upper middle class. More precisely, instead of adopting the simple difference method just described, they compare changes in the incomes of the very high incomes (experiencing the largest tax rate changes), to changes in incomes of the middle and upper middle class (experiencing more modest tax changes). This difference-in-differences of (log) incomes is then divided by the corresponding difference-in-differences of (log) net-of-tax rates to obtain an elasticity responses.

¹⁰Saez (2002) documents in detail the fact that we do not observe bunching, as predicted by theory, at the kink points of the tax schedule.

¹¹Feldstein and Feenberg (1996) noted a decrease in top reported incomes from 1992 to 1993 and interpreted this finding as evidence of large behavioral elasticities. As compensation of executives continued to soar throughout the late 1990s, negative long-run elasticity estimates would be obtained by repeating Goolsbee's analysis and comparing incomes in 1992 to those of the late 1990s.

estimate of the form:

$$\hat{e} = \frac{\Delta \log(z^H) - \Delta \log(z^M)}{\Delta \log(1 - \tau^H) - \Delta \log(1 - \tau^M)}$$

where z^H , z^M and τ^H , τ^M denote the incomes and marginal tax rates of the high (H) and middle (M) income groups respectively; and Δ denotes the changes from before to after the tax change. But suppose that the middle class has a zero elasticity so that $\Delta \log(z^M) = 0$ and that high income individuals have an elasticity of e so that $\Delta \log(z^H) = e\Delta \log(1 - \tau^H)$. Assume further that the middle class experiences an increase in its net-of-tax rates that is half as large as that experienced by the high income taxpayers so that $\Delta \log(1 - \tau^M) = 0.5 \cdot \Delta \log(1 - \tau^H)$. Then, the estimated elasticity \hat{e} will be twice the true elasticity e of the high income group, a dramatic upward bias in the estimate. This simple but realistic example shows that it is not appropriate to rely on comparisons of the responsiveness of the reported incomes of the middle and upper income groups when there is a strong suspicion that the behavioral elasticities for the two groups are quite different.

Fourth, the increases in top incomes following the 1980s tax changes might have been due in part to income shifting rather than creation of new income. As we show below, the critical distinction for policy and welfare analysis, is whether the increase in reported incomes comes at the expense of untaxed activities (such as leisure, fringe benefits, perquisites) or taxed activities (such as profits in the corporate sector, future capital gains, deferred compensation such as pensions). Slemrod (1996) points out that part of the surge in top incomes following TRA 1986 was due to a dramatic increase in S-corporation income, suggesting that many business owners switched the legal form of their corporations from subchapter C (facing the corporate income tax on their profits) toward subchapter S (which do not face the corporate tax and whose profits are taxed directly at the individual level) as the top individual income tax rate became lower than the corporate income tax rate by 1988.¹² Carroll and Joulfaian (1997) explore this issue

¹²A C-corporation faces the corporate tax on its profits. Profits are then taxed again at the individual level if paid out as dividends. If profits are retained in the corporation, they may generate capital gains that are taxed at the individual level but in general more favorably than dividends, when they are realized. Profits from S-corporations (or partnerships and sole proprietorships) are taxed directly and solely at the individual level. Distributions from S-corporations to individual owners generate no additional tax. Thus, a S-corporation is fiscally more advantageous than the C-corporation the lower the individual tax rate, the higher the corporate tax

in more detail using a panel of corporations from 1985 to 1990, and confirm Slemrod's (1996) earlier findings. Gordon and Slemrod (2000) perform a systematic study of income shifting by analyzing simultaneously tax changes and reported incomes at the corporate and personal level. In this paper, we analyze in detail the composition of reported individual incomes in order to cast light on the source of the changes in reported incomes following tax reforms.

The early studies by Lindsey (1987) and Feenberg and Poterba (1993) used the large and stratified annual cross-sectional public-use tax return data to document the evolution of top reported incomes. Following Feldstein (1995) influential analysis of the TRA 1986, a number of studies have used panel data to estimate elasticities. The main justification put forward for using panel data instead of repeated cross-sections is that it might alleviate the issue of non-tax related changes in income inequality, as the same individuals are followed from before to after the reform. However, it is plausible to think that an increase in income inequality might be in large part due to high income individuals experiencing larger gains than lower income individuals, in which case a panel analysis does not solve the issue. Furthermore, a tax cut might induce middle incomes to try harder to become rich, and this behavioral response will be missed by a Feldstein type panel data analysis.

The use of panel data has two additional important drawbacks. First, the publicly available panel of tax returns is not stratified, and hence does not allow nearly as precise a study of the evolution of top incomes as the large stratified cross-sections.¹³ Second, comparing groups ranked according to pre-reform incomes generates a mean reversion problem: if there is mobility in incomes from year to year, then it can cause high income taxpayers in one year to appear low income in the next, aside from any true behavioral response.¹⁴ Eliminating this mobility bias requires to control for pre-reform income in the estimation but this will weaken and possibly destroy identification as the size of net-of-tax rates changes is closely correlated with income.¹⁵

rate, and the higher the capital gains tax rate (see Scholes (1992), Chapter 4, for extensive details and examples). A business can switch to and from the C and S status but S-corporations cannot have more than a limited number of stock-holders (75 currently), issue more than one class of stock, or be a subsidiary of other corporations.

¹³Auten and Carroll (1999) have used a larger panel available only at the Treasury to compare years 1985 and 1989. It is, however, difficult to create longer panels to analyze longer term time series because of attrition issues.

¹⁴This would generate a downward bias in the elasticity estimates in the case of a tax rate decrease such as TRA 1986 and an upward bias in the case of a tax rate increase such as OBRA 1993.

¹⁵This point is discussed in Gruber and Saez (2002) who overcome this problem by using many years instead

Many authors, including Lindsey (1987) himself, have argued that comparing income groups using repeated cross-sections is a valid strategy only if taxpayers stay in the same groups from year to year. However, following a tax rate cut such as ERTA 1981 or TRA 1986, one would like to know how the distribution of reported income has changed relative to a scenario where the tax change does not take place. Whether or not there is mobility in incomes from year to year is independent of this question, as long as the income distribution is stationary (absent the tax change). In contrast, mobility in incomes is precisely what complicates the panel data analysis. Panel data, however, have key advantages to study some questions more subtle than the overall response of reported incomes. For example, if one wants to study how a tax change affects income mobility (for example, do more middle incomes become successful entrepreneurs following a tax rate cut?), panel data is clearly necessary.

Measuring the tax induced change in the income distribution is exactly what is needed to derive the tax revenue consequences of the tax change. Because we do not observe the counterfactual income distribution when no tax change takes place, we have to rely on income distributions from previous years, and there is no systematic bias in the repeated cross-section analysis as long as the income distribution remains stationary, absent the tax change. The direct focus on the income distribution series over-time allows a much more concrete and simple grasp on the evolution of incomes for different groups than panel analysis, as it is straightforward to divide the population into various percentiles for each year, and analyze simultaneously the evolution of the incomes and the marginal tax rates of these groups. By relating the changes in incomes to the changes in net-of-tax rates, we can obtain elasticity estimates.

Finally, Slemrod (1998) and Slemrod and Kopczuk (2002) make the important point that the elasticity of reported incomes with respect to tax rates might not be a fixed parameter and depends on the legal details and the enforcement of the tax system: for example, if it is easy for corporations to switch from subchapter C to subchapter S to avoid taxes, the individual tax base might be much more elastic than in a setting where subchapter S corporations do not exist. Kopczuk (2003) performs an empirical analysis of this issue for the United States from 1979 to 1990, and shows that taxable income elasticities are negatively related to the base of incomes of just two in the analysis. The implicit assumption they need to make, however, is that mobility remains stable from year to year.

subject to taxes. This results suggests that introducing additional deductions increases the responsiveness of taxable incomes. Goolsbee (1999) studies the key tax changes in the United States since the 1920s and finds enormous heterogeneity in the observed responses from episode to episode, although he does not try to explain the discrepancies. The present analysis of the period 1960-2000 also displays significant heterogeneity in responses over time.

2.2 Using Elasticities for Tax Policy

The empirical analysis that follows will show that evidence of behavioral responses to changes in marginal tax rates is concentrated in the top of the income distribution, with little evidence of any response for the middle and upper-middle income class.¹⁶ Therefore, it is useful to focus on the analysis of the effects of increasing the marginal tax rate on the upper end of the income distribution. Let us therefore assume that incomes in the top bracket, above a given threshold \bar{z} , face a constant marginal tax rate τ .¹⁷ We denote by N the number of taxpayers in the top bracket.

We assume that incomes reported in the top bracket depend on the net-of-tax rate $1 - \tau$, and we denote by $z(1 - \tau)$ the *average* income reported by taxpayers in the top bracket. As discussed above, we assume away income effects in the analysis and thus the net-of-tax rate is the only relevant parameter. The elasticity (compensated or uncompensated, as there are no income effects) of income in the top bracket with respect to the net-of-tax rate is therefore defined as $e = [(1 - \tau)/z]\partial z/\partial(1 - \tau)$. Suppose that the government increases the top tax rate τ by a small amount $d\tau$ (with no change in the tax schedule for incomes below \bar{z}). This small tax reform has two effects on tax revenue. First, there is a mechanical increase in tax revenue due to the fact that taxpayers face a higher tax rate on their incomes above \bar{z} . Hence, the total mechanical effect is

¹⁶The low end of the income distribution is out of the scope of the present paper because many low income families and individuals do not file income tax returns. The large literature on responses to welfare and income transfer programs targeted toward low incomes has, however, displayed evidence of significant labor supply responses (see e.g., Meyer and Rosenbaum, 2001 for a recent analysis).

¹⁷In the case of year 2003 tax law, for example, taxable incomes above $\bar{z} = \$311,950$, are taxed at the top marginal tax rate of $\tau = 38.6\%$.

$$dM = N[z - \bar{z}]d\tau.$$

This mechanical effect is the projected increase in tax revenue, absent any behavioral response.

Second, the increase in the tax rate triggers a behavioral response which reduces the average reported income in the top bracket by $dz = -e \cdot z \cdot d\tau / (1 - \tau)$ on average and hence produces a loss in tax revenue equal to

$$dB = -N \cdot e \cdot z \cdot \frac{\tau}{1 - \tau} d\tau.$$

Summing the mechanical and the behavioral effect, we obtain the total change in tax revenue due to the tax change:

$$dR = dM + dB = Nd\tau(z - \bar{z}) \cdot \left[1 - e \cdot \frac{z}{z - \bar{z}} \cdot \frac{\tau}{1 - \tau} \right].$$

Let us denote by a the ratio $z/(z - \bar{z})$. Note that $a \geq 1$ and that $a = 1$ when $\bar{z} = 0$, that is, when there is a single flat tax rate applying to all incomes. If the top tail of the distribution is Pareto distributed,¹⁸ then the parameter a does not vary with \bar{z} and is exactly equal to the Pareto parameter. As the tails of actual income distributions are very well approximated by Pareto distributions, it turns out that the coefficient a is extremely stable for \bar{z} above \$200,000. Saez (2001) provides such an empirical analysis for 1992 and 1993 incomes using tax return data. The parameter a measures the thinness of the top tail of the income the distribution: the thicker the tail of the distribution, the larger is z relative to \bar{z} , and hence the smaller a . Feenberg and Poterba (1993) provide estimates of the Pareto parameter a from 1951 to 1990 for the distribution of AGI in the United States using income tax returns and show that a has decreased from about 2.5 in the early 1970s to around 1.5 in the late 1980s.¹⁹

We can rewrite the effect of the small reform on tax revenue dR simply as:

¹⁸A Pareto distribution has a density function of the form $f(z) = C/z^{1+\alpha}$ where C and α are constant parameters. α is called the Pareto parameter.

¹⁹Piketty and Saez (2003) provide estimates of thresholds \bar{z} and average incomes z corresponding to various fractiles within the top decile of the U.S. income distribution from 1913 to 2000, allowing a straightforward estimation of the parameter a for any year and income threshold.

$$dR = dM \left[1 - \frac{\tau}{1 - \tau} \cdot e \cdot a \right]. \quad (1)$$

Formula (1) is of central importance. It shows that the fraction of tax revenue lost through behavioral responses – the second term in the square bracket expression – is a simple function increasing in the tax rate τ , the elasticity e , and the Pareto parameter a . This expression is also equal to the marginal deadweight burden created by the increase in the tax rate. More precisely, because of the envelope theorem, the behavioral response creates no additional welfare loss as the individual is maximizing utility, and thus the utility loss (in dollar terms) created by the tax increase is exactly equal to the mechanical effect dM . However, tax revenue collected is only $dR = dM + dB$ with $dB < 0$. Thus $-dB$ represents indeed the extra amount lost in utility over and above the tax revenue collected dR . The marginal excess burden expressed in terms of extra taxes collected is simply

$$-\frac{dB}{dR} = \frac{e \cdot a \cdot \tau}{1 - \tau - e \cdot a \cdot \tau}. \quad (2)$$

Those formulas are valid for any tax rate τ and income distribution, even if individuals have heterogeneous utility functions and behavioral elasticities.²⁰ as long as income effects are assumed away. Thus, this formula should be preferred to the Harberger triangle approximations which require small tax rates to be valid. The parameters τ and a are straightforward to obtain, the elasticity parameter e is thus the central non-trivial parameter necessary to make use of formulas (1) and (2). For example, in 2000, for the top .5% income cut-off (corresponding approximately to the top 39.6% federal income tax bracket in that year), Piketty and Saez (2003) estimate that $a = 1.6$. For an elasticity estimate $e = 0.5$, corresponding to the mid to upper range of the estimates from the literature, the fraction of tax revenue lost through behavioral responses (dB/dM), should the top tax rate be slightly increased, would be 52.5%, more than half of the mechanical projected increase in tax revenue. In terms of marginal excess burden, increasing tax revenue by \$1 requires to create a utility loss of $1/(1 - .525) = \$2.11$ for taxpayers, and hence a marginal excess burden of \$1.11 or 111% of the extra \$1 tax collected.

Following the supply-side debates of the early 1980s, much attention has been focused on the tax rate maximizing tax revenue, the so-called ‘‘Laffer rate’’. The Laffer rate τ^* maximizes tax

²⁰The elasticity e is the average (income weighted) of individual elasticities.

revenue, hence the bracketed expression in equation (1) is exactly zero when $\tau = \tau^*$. Rearranging the equation, we obtain the following simple formula for the Laffer tax rate τ^* for the top bracket:

$$\tau^* = \frac{1}{1 + a \cdot e}. \quad (3)$$

A top tax rate above the Laffer rate is a very inefficient situation because decreasing the tax rate would both increase government revenue and the utility of high income taxpayers.²¹ At the Laffer rate, the excess burden becomes infinite as raising more tax revenue becomes impossible. Using our previous example with $e = 0.5$ and $a = 1.6$, the Laffer rate τ^* would be 55.6%, not much higher than the combined maximum federal, state, medicare, and sales tax rate. Note that when $\bar{z} = 0$, and the tax system has a single tax rate, the Laffer rate becomes the well-known expression $\tau^* = 1/(1 + e)$. As $a \geq 1$, the flat rate maximizing tax revenue is always larger than the Laffer rate for high incomes only. This is because increasing the top tax rate collects extra taxes only on the portion of incomes above the bracket threshold \bar{z} but produces a behavioral response for high incomes as large as an across the board increase in marginal tax rates.

The analysis has assumed so far that the reduction in incomes due to the tax rate increase has no other effect on tax revenue. This is a reasonable assumption if the reduction in incomes is due to reduced labor supply (and hence an increase in untaxed leisure time), or due to a shift from cash compensation toward untaxed fringe benefits or perquisites (more generous health insurance, better offices, company cars, etc.). However, in many instances, the reduction in reported incomes is due in part to a shift away from individual income toward other forms of taxable income such as corporate income, or deferred compensation, that will be taxable to the individual when paid out (see Slemrod, 1998). For example and we will come back to this later on in detail, Slemrod (1996) and Gordon and Slemrod (2000) show convincingly that part of the surge in top incomes after the Tax Reform Act of 1986 was due to a shift of income from the

²¹In the case where the government has strong redistributive tastes and does not value the marginal consumption of high income individuals relative to the average individual, the optimal income tax rate for high incomes is exactly equal to the Laffer rate (3). In the general case where the government values the marginal consumption of high incomes at $0 \leq g < 1$, the optimal tax rate for the high incomes is such that the bracketed expression in (1) is equal to g . See Saez (2001) for a more detailed exposition following the classical optimal income tax theory of Mirrlees (1971).

corporate sector toward the individual sector.

Let us therefore assume that the incomes that disappear from the individual income tax base following the tax rate increase $d\tau$ are shifted to other bases taxed at rate t on average. For example, if two thirds of the reduction in individual reported incomes is due to increased leisure and one third is due to a shift toward the corporate sector, t would be one third of the corporate tax rate, as leisure is untaxed. In that case, it is straightforward to show that formula (1) becomes:

$$dR = dM \left[1 - \frac{\tau - t}{1 - \tau} \cdot e \cdot a \right]. \quad (4)$$

The same envelope theorem logic applies for welfare analysis and the marginal deadweight burden formula is also modified accordingly by replacing $e \cdot a \cdot \tau$ by $e \cdot a \cdot (\tau - t)$ in both numerator and denominator of (2). The Laffer rate (3) becomes:

$$\tau^* = \frac{1 + t \cdot a \cdot e}{1 + a \cdot e}. \quad (5)$$

If we assume again that $a = 1.6$ and $e = .5$, but that incomes disappearing from the individual base are taxed at $t = 20\%$ on average, the fraction of revenue lost due to behavioral responses drops from 52.5% to 26%, and the marginal excess burden (expressed as a percentage of extra taxes raised) decreases from 111% to 35%, if the initial top tax rate is $\tau = 39.6\%$. The Laffer rate increases from 55.6% to 64.5%. This simple theoretical analysis shows therefore, that, in addition to estimating the elasticity e , it is critical to analyze the source or destination of changes in reported individual incomes.

2.3 Data and Methodology

We estimate the level and shares of total income accruing to various upper income groups using the large cross-sectional individual tax return data annually released by the IRS since 1960.²² The data are a stratified sample of tax returns oversampled for high-income taxpayers, allowing an extremely precise analysis of top reported incomes. The top income shares are estimated

²²There is no micro data for years 1961, 1963, and 1965.

based on the Piketty and Saez (2003) analysis.²³ The unit of analysis is the tax unit defined as a married couple living together (with dependents) or a single adult (with dependents), as in the current tax law. It is important to keep in mind that top income shares series measured at the tax unit level, as we do here, might be different from series estimated at the individual level. As displayed in Table A, since 1960, the average number of individuals per tax unit has decreased from 2.6 to 2.1 due to the decrease in the average number of dependent children per tax unit as well as the decrease in the fraction of married tax units. Those long-term demographic changes imply that real average income growth per tax unit will be substantially smaller than real income growth per capita. These demographic changes can also affect top income shares if the reduction in tax units size is not uniform across income groups. However, the tax return data show that the reduction in tax unit size has been about the same for high incomes than for the U.S. population as a whole. From 1960 to 2000, the number of individuals per tax unit in the top decile has declined from 3.6 to 2.9, which is the same 20% decline as in the general population (from 2.6 to 2.1).

From 1960 to 2000, the fraction of married tax units has declined from about 60% to 50% for the population at large (due to the increased number of single parents and non married couples) but only from 90% to 85% for the top decile tax units. An increase in single tax units with lower incomes contributes to increasing top income shares. Similarly, an increase in the correlation of earnings between spouses (due for example to increased labor force participation of married women) would also increase top income shares estimated at the tax unit level. Those slow moving demographic changes, however, are small relative to the dramatic trends we document and can only explain at best a very small fraction of the changes in the very top income shares.

Each upper income group is defined relative to the total number of potential tax units in the entire U.S. population, estimated from population and family census data as the sum of married men, divorced and widowed men and women, and of single adults never married (aged 20 and above).²⁴ The income definition we use is consistent over time and includes all income

²³The main (and very minor) difference is that government transfers such as Social Security benefits and Unemployment Compensation have been excluded from the income definition in this paper in order to obtain better consistency in the income definition over years. The estimates have been extended to year 2000.

²⁴From 1960 to 2000, between 90 and 95% of potential tax units actually filed an income tax return, as many non-taxable families file in order to get tax refunds.

items excluding realized capital gains²⁵ reported on tax returns and before all deductions such as adjustments to gross income, exemptions, itemized and standard deductions. We exclude government transfers such as Social Security (SS) benefits and Unemployment Insurance (UI) benefits. Thus, our income measure is defined as Adjusted Gross Income (AGI) less realized capital gains included in AGI, less taxable SS and UI benefits, plus all the adjustments to gross income. Hence, our measure of income is a broader measure than taxable income on which many previous studies have focused. If deductions to income such as charitable giving, mortgage interest payments, etc. are also responsive to taxation, taxable income might be more responsive to tax rates than our broader income measure. However, as the nature of deductions allowed has changed substantially over the period 1960-2000, it is impossible to construct a consistent taxable income definition over the full period. As a result, we refer the reader to previous studies analyzing specifically the components of taxable income that we exclude from the analysis.

As in Piketty and Saez (2003), we consider various groups within the top decile of the income distribution. In order to get a more concrete sense of those upper income groups, Table 1 displays the thresholds, the average income level in each group, along with the number of tax units in each group, all for 2000. The median income, as well as the average income for the bottom 90% of tax units is quite low, around \$25,000. Those numbers are smaller than those reported by the Census Bureau based on the Current Population Survey (CPS) for two reasons. First, our income definition does not include any government transfers. Second, CPS income is reported at the household level which is a larger unit than the tax unit we consider.²⁶

The groups in the top decile below the top 1% (the top 10-5% denotes the bottom half of the top decile, and the top 5-1%, the next 4 percentiles) have average incomes of \$100,000 and \$160,000 respectively, which corresponds, perhaps surprisingly given how far up the income distribution those groups are, to the popular view of the middle and upper middle income class. In 2000, an annual family income of at least \$280,000 is required to be part of the top 1%. Hence, the top 1% corresponds perhaps to the popular view of the high incomes. About 140,000 tax units (or slightly more than 0.1% of all tax units) report incomes larger than one million

²⁵Realized capital gains are excluded because they form a very volatile component of income and face in general a different tax treatment than other forms of income. There is a large literature focusing on the response of capital gains realizations to tax changes. See Auerbach (1988) for a survey.

²⁶For example, a cohabiting couple or two roommates form a single household but two tax units.

dollars (the very high incomes). Finally, the top .01%, the smallest top group we consider, is formed by the top 13,400 tax units, reporting on average \$13 million of annual income in 2000, these are the super high income American families.

We estimate shares of income by dividing the income amounts accruing to each group by reported income, where we have assumed that non-filing units earn 20% of the average income.²⁷ We then estimate the composition of income for each group and we consider seven components: salaries and wages (including exercised stock-options, bonuses, and private pensions), S-corporation income, sole proprietorship (Schedule C income) and farm income, partnership income, dividends, interest income, and other income (including smaller items such as rents, royalties, and other miscellaneous items).

Marginal tax rates are estimated using the TAXSIM tax calculator. For each individual record, we compute a weighted marginal tax rate based on wage income and other income as various provisions in the tax code generate differences in the tax treatment of wage income and other forms of income. For each income group, we then estimate an average marginal tax rate weighted by income.²⁸ It is important to note that our marginal tax rate computations ignore state income taxes because the data does not provide state information for high income earners. Our tax measure also ignores other taxes such as social security and medicare taxes, corporate taxes, and non-income taxes such as sales and excise taxes.

We use the same methodology to compute top wage shares using wages and salaries reported on tax returns. Wages and salaries include exercised stock-options and bonuses. In this case, groups are defined relative to the total number of tax units with positive wage income estimated as the number of part-time and full workers from the National Income and Product Accounts less the number of married women who are employees. The sum of total wages in the economy used to compute shares is obtained from National Income and Product Accounts (total compensation of employees). The marginal tax rates for upper wage income groups are of course those relevant for wages and salaries and are also weighted by wage income (see Table A).

We propose a very simple time series regression methodology to obtain various elasticity estimates, and illustrate some of the identification difficulties. Because of potential heterogene-

²⁷As only between 5 and 10% of tax units do not file returns, our results are not sensitive to this assumption.

²⁸As we saw above, for tax policy analysis, it is necessary to weight marginal tax rates by income.

ity in elasticities across income groups, all our regressions are run for a single income group. The simplest specification consists in regressing log real incomes on log net-of-tax rates (and a constant) for a given group. Of course, as real incomes grow over time, we can add time trends in the regression to control for exogenous (i.e., non-tax related) real income growth. Those estimates are unbiased estimates of behavioral elasticities, if absent any tax change, real incomes in that specific group do not change (first specification) or follow a regular time pattern (second specification). These assumptions may not be met. As many years of data are included, these estimates capture mostly the long-term behavioral elasticities.²⁹ As we will see, the pattern of average incomes for the full population does not appear to be related to the evolution of average marginal tax rates, therefore, in order to control for average income growth, we run most of the regressions in terms of log income shares instead of log average incomes.³⁰ Those regressions control automatically for overall income growth. Adding time trends in that case amounts to assuming that incomes for the particular group considered may diverge from the average income in the economy. As we are running time-series regressions and the error terms appear to be correlated over time (according to the standard Durbin-Watson test), OLS standard errors are not correct. Therefore, we compute the Newey-West standard errors assuming that the error terms can be correlated up to an eight year lag.³¹

Due to the progressive structure of the income tax, increases in incomes lead to higher marginal tax rates because of bracket-creep. As a result, an increase in top income shares (for non-tax related reasons) might also induce a mechanical increase in the marginal tax rate faced by those high incomes, hence potentially biasing downward our elasticity estimates. A simple way to investigate the extent of the problem is to use the statutory top marginal income tax rate (or more precisely the log of one minus the top rate) as an instrument for the effective log net-of-tax rate variable. Our results show that the OLS and IV estimates are extremely close, suggesting that this bracket-creep issue does not create a significant estimation problem.

²⁹We leave for future research the regression analysis of the dynamics of tax responses. Such a formal analysis has been attempted in the case of capital gains realizations (see, e.g., Auerbach, 1988).

³⁰Slemrod (1996) adopted the same approach, although he controlled for non-tax factors explicitly rather than using general time trends controls as we do here.

³¹An eight year lag is close to maximizing the size of the standard errors, and thus should be seen as conservative.

3 Income Shares and Marginal Tax Rates

3.1 Trends in Average Incomes

We depict on Figure 1, the average federal marginal individual income tax rate (weighted by income) and the average income (per tax unit) reported in real terms for the full population from 1960 to 2000. Incomes are expressed in 2000 dollars using the standard CPI-U deflator (see Table A). Figure 1 shows that real incomes increased quickly from 1960 to 1973 and then hardly increased until the early 1990s. From 1993 to 2000, real incomes have increased quickly but are only 13% higher than in 1973. Real growth depends critically on the CPI deflator. Improvements in the CPI estimation have been made over the years and some of them have been incorporated retrospectively in the so-called CPI-U-RS deflator (see Stewart and Reed, 1999). Using the CPI-U-RS instead of the CPI-U would display about 29% real income growth instead of 13% from 1973 to 2000 (see Table A).

Average marginal tax rates display significant movements with a steady increase from 21-22% to 30% from the mid 1960s to the early 1980s (with a temporary surge during the Vietnam war surtaxes in 1968-70). In the 1980s, the average marginal tax rate decreased to 23%, and increased slightly to 26% during the 1990s. Figure 1 displays no clear relation between the level of real incomes and the level of marginal tax rates. As displayed in Table 2, Panel A, a simple OLS regression of log average incomes on the log of the net-of-tax rate controlling or not for time trends to account for exogenous economic growth, display insignificant elasticity coefficients. Therefore, the aggregate data displays no evidence of significant behavioral responses of reported incomes to changes in the average marginal tax rate.

Figure 2 shows a striking contrast between the bottom 99% tax units (Panel A) and the top 1% (Panel B). The average real income of the bottom 99% increased steadily from 1960 to 1973 and then stagnated: real incomes in 2000 are hardly higher than in 1973.³² The decline in marginal tax rates faced by the bottom 99% from almost 30% in 1981 to around 23% in 2000 does not seem to have noticeably improved the growth of real incomes. Indeed as shown in Table

³²If one uses the CPI-U-RS deflator, the bottom 99% real incomes would have grown by about 13%. In any case, it is clear that real growth of incomes has been very slow in last quarter of the 20th century relative to the 1950-1973 period. It is also important to note that this slow growth is not due to a decrease in the number of adults per tax units (see Table A).

2, Panel B, regressing the log average incomes on the log net-of-tax rate for the bottom 99% displays negative (although insignificant) coefficients whether or not a time trend is included.

In stark contrast, the average real income of the top 1% has increased by 160% since the early 1970s (or by 200% if one uses the CPI-U-RS), and the average marginal tax rate has also declined substantially, from around 50% before 1981 to less than 30% by 1988. It is striking to note that the top 1% incomes start increasing precisely in 1981 when marginal tax rates start going down. The jump in top incomes from 1986 to 1988 corresponds exactly to the sharp drop in marginal tax rates from 45% to 29% after the Tax Reform Act of 1986. These points, first noted by Poterba and Feenberg (1993), suggest that high incomes are indeed quite responsive to taxation. The other striking feature of the figure is the extraordinary increase in top incomes from 1994-2000 in spite of the increase in tax rates from about 32% to almost 40% in 1993. Thus, although the marginal tax rates faced by the high incomes in 2000 are hardly lower than in the mid-1980s (39% instead of 44-45%), top incomes are more than twice larger.

Figure 2 illustrates very well the difficulty of obtaining convincing estimates of the elasticity of reported income with respect to the net-of-tax rate. It seems clear that the sharp, and unprecedented, increase in incomes from 1986 to 1988 is related to the large decrease in marginal tax rates that happened exactly during those years. The central question, however, is whether this short-term response persists overtime. In particular, how should we interpret the continuing rise in top incomes in since 1994? If one thinks that this surge is evidence of diverging trends between high incomes and the rest of the population independent of tax policy, which started in the 1970s, then it is tempting to consider the response of TRA 1986 as a purely short-term spike followed by lower growth from 1988 to 1993, before getting back to the normal upward trend by 1994. On the other hand, one could argue that the surge in top incomes since the mid-1990s might have been the long-term consequence of the decrease in tax rates in the 1980s and that such a surge would not have occurred, had high incomes tax rates remained high as in the 1960s and 1970s. We come back to this point later on.

Those issues are illustrated formally in the regression results of Table 2, Panel C. When no time trend is included in the regression of log income on log net-of-tax rate, all the growth in top incomes is attributed to the decline in top rates, and the elasticity obtained is extremely large 1.83 (.37). In contrast, including a time trend produces a much smaller, although still sizeable,

elasticity .71 (.22) because part of the rise in top incomes is attributed to a secular rise. Adding an additional time square control further reduces the elasticity to 0.5 (0.18).

This analysis also shows that, comparing two single years by taking the ratio of the difference in log incomes to the difference in log net-of tax rates, as done in most studies, can produce a wide range of elasticity estimates. Comparing 1981 to 1984, as in Lindsey (1987), would produce an elasticity of 0.77.³³ Comparing 1985 and 1988, as in Feldstein (1995) and Auten and Carroll (1999), would produce an extremely large 1.7 elasticity.³⁴ In contrast, comparing 1991 to 1994 (as in Goolsbee, 2000a) would produce a zero elasticity because top incomes are about constant while tax rates increase by almost 10 percentage points.³⁵ The elasticity would even become negative if one compares 1991 to the late 1990s as both top incomes and the tax rate have increased.³⁶ The large micro-data sets can be used to obtain those simple elasticity estimates directly from regressions at the individual level as done in many studies, with very small standard errors. The regression counterpart would be to pool the samples of top 1% earners for the pre and post reform years, and run a 2SLS regression of log incomes on log net-of-tax rate using as an instrument a post year dummy.³⁷ In order to cast further light on those issues and try to separate tax effects from other effects, we turn to a closer analysis of various upper income groups, with particular emphasis on the change in the composition of reported incomes.

³³Lindsey obtains larger estimates because he compares the upper income to the middle income groups, creating an upward bias if, as is apparent in the data, elasticities are increasing with income (see discussion above).

³⁴Auten and Carroll (1999) obtain a much smaller 0.6 elasticity because they compare 1985 to 1989 (instead of 1988 as Feldstein) and because of the mean reversion issue discussed above which is difficult to correct with only two years of data.

³⁵In contrast, comparing 1992 to 1993 would produce a significant short-term elasticity of 0.63 as in Feldstein and Feenberg (1996).

³⁶Carroll (1998) and Sammartino and Wiener (1997) analyze panel tax return data also show that short term responses around OBRA 1992 are much larger than longer term responses.

³⁷It is doubtful, however, that those small standard errors would be accurate, as random year effects are most likely to be present in the data making 2SLS standard errors far too low and hence worthless (in addition to creating the identification problems discussed above). See Bertrand, Duflo, and Mullainathan (2003) for a detailed discussion of those econometric issues.

3.2 Trends in Top Income Shares and Marginal Tax Rates

We have shown that average real incomes do not seem to respond to average marginal tax rates in the aggregate, and that responses seem to be concentrated in the upper 1% fraction of the income distribution. Therefore, from now on, we normalize top incomes by considering the shares of total income accruing to various upper groups (as in Feenberg and Poterba, 1993 and 2000, and Piketty and Saez, 2003). This has two advantages. First, the income share measures are independent of the CPI deflator used. Second, the top shares are automatically normalized for overall real and nominal growth in incomes. All our top income share series and corresponding average marginal tax rates (income weighted) are reported in Tables B1 and B2 respectively.

Table 3 displays a number of regressions of the (log) top 1% income share on the log net-of-tax rate, varying the number of time trends controls and instrumenting or not the tax variable with the log net-of-tax top rate. As discussed above, introducing time trends reduces substantially the elasticity (from 1.6 with no controls) to about 0.6-0.7 (with many controls). After adding linear and square controls in time, the adjusted R-square reaches 98% and the elasticity coefficient is not sensitive to adding further controls. The IV estimates are very close in magnitude to the OLS estimates and have a strong first stage (except in the case of col. (4) where the first stage is weak), suggesting that the issue of reverse causality because of the progressive nature of the tax schedule is not an important issue. Figure 3 illustrates those issues by plotting, along with the top 1% income share series, the fitted values from the regressions with no time controls (dotted line) and with two time controls (solid line). The dotted line shows that the pure tax effects explain quite poorly the evolution of the top 1% income share. In contrast, the solid line with two time trends captures extremely well the pattern of the top 1% income share (the adjusted R-square of the regression is 98%). The dashed line in Figure 3 displays the counterfactual pattern assuming that the marginal tax rate for the top 1% had remained constant since 1960. This curve shows that most of growth in the top 1% income share is due to the time trends and that only 2 out of the 9 percentage point increase in the top 1% income share from the 1960s to 2000 is due to the decline in marginal tax rates. Therefore in summary, attributing all the increase in the top income shares to the tax developments generate very large elasticities but fits the data poorly. Controlling for time trends fits the data much better and reduces substantially the elasticity as well as the fraction of the increase in top incomes that can be attributed to tax

changes.

Figure 4 displays the share of income accruing to the bottom half of the top decile (Panel A), and the bottom half of the top percentile (Panel B), along with the average marginal tax rate faced by those two groups. The figure shows that the top 10-5% income group has experienced very moderate gains since 1960 and the pattern of the gains does not appear to be correlated with the pattern of the marginal tax rates they face (rising up to 1981, then declining in the 1980s, and then stable in the 1990s). Panels A and B in Table 4 show that regressing the log of the top income shares of the top 10-5% and top 5-1% on their log net-of-tax rates, with or without time trend controls produces elasticities very close to zero. Therefore, upper middle income families and individuals (up to the top 1% threshold around \$280,000 per year in 2000) do not appear to be sensitive to taxation.³⁸ It is striking, in particular, that those upper middle income class shares increase very little during the 1980s although they experience quite sizeable marginal tax rate cuts (about 9 percentage points for the top 10-5%, and over 13 points for the top 5-1%).³⁹ Note again that IV estimates are also virtually identical to OLS estimates.

Interestingly, Panel B of Figure 4 shows that the top 1-5% share does not decrease during the 1970s when the marginal tax rate increases from 40 to 50% and does not increase during ERTA 1981 when the marginal tax rate decreases back to 40%. In contrast, TRA 1986, which decreases the rate to around 32% (thus a smaller percentage change in the net-of-tax rate relative to the 1970s or ERTA 1981) does produce a sizeable increase in the income share, producing a noticeable break in the series. The increase in tax rates to about 38% following OBRA 1992 does not seem to have affected the upward trend following TRA 1986. Thus although marginal tax rates in the late 1990s are about the same as in the 1960s, the income share is 30% larger.⁴⁰

³⁸In principle, the secondary earner labor supply responses should be captured by those elasticities. Thus our results can be consistent with the large married women labor supply responses obtained by Eissa (1995) only if secondary earners income is a small fraction of total reported family incomes.

³⁹A similar regression analysis for other income groups below the top decile generates small or even negative and always insignificant elasticities. The estimates, however, are not very precisely estimated as changes in net-of-tax rates are much smaller below the top decile.

⁴⁰Those considerations show again that elasticity estimates would be extremely sensitive to the time period considered. The ERTA 1981 and OBRA 1993 episodes would produce zero elasticity estimates, and TRA 1986 would produce a sizeable 0.93 estimate (comparing 1986 and 1988). Comparing 2000 to 1984 and attributing all the large increase in the share to the modest decrease in marginal tax rate would produce an enormous elasticity

The regressions for the groups top 1-.5% and top .5-.1% in Table 4 (Panels C and D) display significant elasticities but the size of the elasticity is much smaller when income controls are included.

Figure 5 displays the share of income and marginal tax rates for the very top groups: top .1-.01% (Panel A), and the top .01% (Panel B). The responses to ERTA 1981, TRA 1986, and the short-term response to OBRA 1993 followed by a surge in income shares since 1995, are even more pronounced than for the groups just below. However, the Kennedy tax cuts of the early 1960s provide striking new evidence. For the very top .01%, the very progressive tax structure of the early 1960s generated extremely high marginal tax rates (around 80%) which were reduced significantly by the Kennedy tax cuts in 1964-5 (to about 65%).⁴¹ This implies a 75% increase in the net-of-tax rate, a much larger increase than the ERTA 1981 and TRA 1986 tax rate reductions. In spite of this enormous marginal tax rate cut, the very top share remains flat in the 1960s, and well into the 1970s, suggesting a complete absence of behavioral response in both the short and the long-run.⁴² Note that, although the top nominal marginal tax rate was 91%, the average marginal tax rate of the top .01% is “only” slightly above 80%. This is due to various other provisions of the tax code such as the maximum average tax of 87% on income and charitable gifts by the very wealthy.⁴³ Table 4 (Panels E and F) show that the regressions for the top .1-.01% and the top .01% display significant elasticities in all specifications, although pure tax factors can only explain a fraction of the total increase in the very top shares once exogenous time trends are included.

estimate of 4.94.

⁴¹Those tax cuts were proposed by president Kennedy in the early 1960s but were actually implemented by the Johnson administration after Kennedy’s death in 1963.

⁴²Lindsey (1990) claimed that the Kennedy tax cuts generated a surge in top incomes, but this erroneous result is due to his very casual examination of the tabulations published by the IRS. Goolsbee (1999) makes a more careful use of the same published data (although he does not exclude realized capital gains and does not measure marginal tax rates very accurately) and finds no response, as we do here.

⁴³Considering smaller groups at the very top, such as the top .001%, never generates marginal tax rates higher than 80-82%.

3.3 Composition

We have seen in the previous subsection that the income groups within the top decile display very heterogeneous responses. Groups below the top 1% never display evidence of tax responsiveness. Top groups display a sharp response to the 1980s tax cuts, and especially TRA 1986, but only a short-term response to the tax increase of 1993, and no response for the earlier tax cuts in the 1960s. In order to cast further light on these findings, we now turn to an analysis of the composition of those incomes.⁴⁴ The complete composition series of top income groups are reported in Tables D1 and D2 of the longer working paper version Saez (2004).

Figure 6 displays the evolution of the top decile income share, and how those incomes are decomposed into the seven sources described in Section 2, from 1960 to 2000. Wage income forms the majority of the top 10% incomes, and its share has increased smoothly from two thirds to about three quarters since 1960. Interesting, the large 12 percentage point gain in the top 10% income share (from 32% to 44%) is due almost entirely to a smooth and secular increase in the wage component (from 22 points to 33.5 points), with the size of the other components remaining stable overall (around 10 points with a squeeze around 7 points in the late 1970s and early 1980s).

As depicted in Figure 7, the top 1% income share increases from 8.3% to almost 17% from 1960 to 2000. The striking feature, however, is that 7 out of the 8.7 point increase in the top 1% share is due to the wage income component. As a result, although wages represented only 40% of total income of the top 1% in the early 1960s, they now represent over 60% of top 1% incomes. The increase in the wage component appears to have started in the early 1970s and has been fairly regular with an acceleration in the last two decades (especially the 1990s). There are two spikes in the wage component series, one in 1988 (just after TRA 1986), and another in 1992 (just before the OBRA 1993 tax increase). However, the short-term nature of those two spikes suggests that they were the consequence of re-timing of wage income to take advantage of lower rates.⁴⁵

⁴⁴The previous literature has mostly focused on taxable income elasticities. Feenberg and Poterba (1993,2000) analyze the composition of incomes for the top .5% from 1951 to 1990 and Slemrod (1994,1996) analyze the composition of top incomes around TRA 1986.

⁴⁵Goolsbee (2000a) showed that executives exercised massively their stock-options in 1992 in order to take advantage of the low rate of 31% in 1992 before the increase to 39.6% in 1993. This re-timing explains the large

Although the non-wage part stays stable as a whole, the components display interesting patterns. The most striking feature is the emergence of S-corporation income after TRA 1986. Before the 1980s, S-corporation income was extremely small, as indeed the standard C-corporation form was more advantageous for high income individual owners because the top individual tax rate was much higher than the corporate tax rate and taxes on capital gains were relatively low. S-corporation income increases sharply from 1986 to 1988 and increases slowly afterwards. The sharp increase in S-corporation income just after TRA 1986 certainly reflects in large part a shift in the status of corporations from C to S status to take advantage of the lower individual rates.⁴⁶ In contrast, dividends (paid out by C-corporations and foreign corporations) and sole proprietorship income decrease regularly over the period. Partnership income is about the same in the 1960s as in the 1990s; partnership income was very small during the 1980s due to dramatic increase in partnership losses.⁴⁷ The dramatic increase of partnership losses from the mid to late 1970s up to 1986 (during recessions and recoveries alike) is probably first due to the increase in inflation which, because of deductibility of nominal interest payments, might have increased losses.⁴⁸ Then, taxpayers and tax accountants might have realized that partnerships offered an attractive possibility to avoid taxes. The repeal of the investment tax credit and the passive losses limitations with the TRA 1986, as well as the reduction in top tax rates, has drastically reduced the value of those tax shelters and probably explains the very quick and sustained disappearance of most partnership losses just after TRA 1986.⁴⁹ Sole proprietorship income also displays a similar pattern, with a sharp reduction from the mid 1970s to the mid 1980s.⁵⁰ Although the wage income component starts to increase in the early 1970s, the combined effect of sharp reductions in partnership and sole proprietorship incomes from the mid-1970s to 1981 income explains why the top 1% income share stays almost flat up to 1981.

Figure 8 displays the income share and composition of the very top .01% group. It shows a

difference between the short-term and long term elasticity estimates using the OBRA 1993 reform.

⁴⁶See Slemrod (1996), Carroll and Joulfaian (1997), and Gordon and Slemrod (2000) for a more precise analysis.

⁴⁷Partnership profits have stayed about stable over the full period.

⁴⁸Note that interest income (which is not net of interest payment deductions) is particularly high during that period as well.

⁴⁹See Samwick (1996) for a more detailed analysis.

⁵⁰Sole proprietorship income displays a secular trend downward from 1960 to 2000, most likely due to the secular decline in farming, and other traditional small business activities organized in the form of sole proprietorships.

dramatic shift in the composition of very top incomes away from dividends (which represented more than 60% of top incomes in the early 1960s) toward wage income (which represents about 60% of top incomes in 2000).⁵¹ In the early 1960s, the top .01% incomes were facing extremely high marginal tax rates of about 80% on average (while tax rates on long-term capital gains were around 25%). Thus, dividends were a very disadvantaged form of income for the rich suggesting that those top income earners had little control over the form of payment, and thus might have been in large part passive investors. The Kennedy tax cuts did not reduce the top individual rate enough (the top rate became 70%) to make the S-corporation form attractive relative to the C-corporation form, explaining perhaps the contrast in behavioral responses between the Kennedy tax cuts episodes and the tax changes of the 1980s. This shows, as argued by Slemrod and Kopczuk (2002), that the elasticity of reported incomes is not a constant parameter but may be extremely sensitive to the legal structure, and the complete tax environment for corporations and individuals. The share of dividends falls regularly over the period while the share of wage income starts to increase in 1971. By 1979, the wage component overtakes the dividend component. Figure 8 shows clearly that ERTA 1981 produced a sudden burst of S-corporation income (which was negligible up to 1981). This is most likely due to a shift from C-corporations to S-corporations.⁵² It is interesting to note that the increase in S-corporation income is concentrated mostly in the top .01% and does not happen at all for groups below the top .1%. This is fully consistent with the tax minimization explanation: ERTA 1981 decreased marginal tax rates significantly only for groups above the top .1% for whom the subchapter S status started to become attractive when the top individual rate was reduced to 50%.⁵³ Figure 8 shows that almost all the increase in top incomes from 1981 to 1984, first documented by Lindsey (1987), is also due to the surge in S-corporation income. The wage component increases as well but with no noticeable break in the upward trend around ERTA 1981.⁵⁴ The S-corporation component increases again sharply from 1986 to 1988, and then stay about stable afterwards.

⁵¹This secular shift from rentiers to the working rich at the top of the U.S. income distribution is described in more detail in Piketty and Saez (2003).

⁵²As discussed above, this phenomenon has been well documented in the case of TRA 1986.

⁵³From 1980 to 1986, the corporate tax rate was 42%.

⁵⁴Because of the maximum tax of 50% on labor income enacted in 1971-2, marginal tax rates for top wage incomes actually did not change much with ERTA, see below.

The wage component also presents a spike in 1988, as well as in 1993, but those spikes seem to be short-term responses in a generally upward trending curve. The tax cuts of the 1960s, although extremely large, did not generate any behavioral response, perhaps because top individual rates remained substantially higher than the corporate and capital gains tax rate and thus did not induce top taxpayers to switch corporate income toward individual income.

Therefore, to sum up, the dramatic increase in top income shares is due primarily to a secular increase in the wage income component starting in the early 1970s, and the large tax changes of TRA 1986 and OBRA 1993 seem to have only generated short-term spikes in the overall upward and accelerating trend of the wage component.⁵⁵ The tax cuts of the 1980s have generated a surge in business income taxed at the individual level. ERTA 1981 created a surge in S-corporation income for the very top groups of the income distribution. With TRA 1986, S-corporation income surged for all upper income groups. Partnership income also rose dramatically immediately after TRA 1986, mostly because of the disappearance of partnership losses. Those business income components have remained relatively stable after TRA 1986, suggesting that they were the consequence of a one-time shift from the corporate sector, and the one-time closing of the partnership loss tax shelters. The top tax rate increase of 1993 to 39.6% (with a corporate tax rate of 35%) was not large enough to induce business owners to switch back to the C-corporation status. As a result, OBRA 1993 did not produce any long term income shifting away from the individual sector and its only effect seem to have been a short-term re-timing of salary income. The surge in business income reported on individual returns in the 1980s cannot be interpreted as a “supply-side” success as most of those individual income gains came either at the expense of taxable corporate income, or could have been obtained from the closing of tax-shelters by imposing stricter rules on losses from passive businesses.⁵⁶ Therefore, success or failure of the tax cuts to generate additional economic activity must be deferred to a

⁵⁵Top income shares are flat before 1981 masking the increase in the wage component, because of a large decline in partnership and sole proprietorship income due perhaps to high interest rates and the development of tax shelters in the 1970s. Partnership income (and to a lesser extent sole proprietorship income), increased back to its early 1970s level immediately after TRA 1986.

⁵⁶It is doubtful that the decrease in tax rates, by reducing the incentives to avoid taxes, was necessary to eliminate abusive partnership losses (as argued for example in Samwick, 1996) because partnership losses were almost non-existent before the late 1970s, a time where tax rates were extremely high.

more precise analysis of the central wage income component, to which we now turn.

3.4 Top Wage Incomes

We have seen that most of the increase in top income shares since the 1970s is actually due to a sharp increase in the wage income component. The time pattern of marginal tax rates for wage income is not the same as the pattern for other forms of income because of the introduction of the maximum tax rate on earned income in 1971 which reduced the top rate for earned income from 70% (the top rate on other income) to 60% in 1971 and then 50% starting in 1972.⁵⁷ This provision became irrelevant in 1982 when the top tax rate for any income source was reduced from 70% to 50%. Therefore, it is of particular interest to analyze separately the wage income component. All our top wage income share series and corresponding average marginal tax rates for wage income are reported in Tables C1 and C2 respectively.

As for average income, the evolution of average real wage income series (for the full population) does not appear to be correlated with the evolution of marginal tax rates. Figure 9 shows the pattern of real incomes and marginal tax rates for the bottom 99% wage earners (Panel A) and the top 1% wage earners (Panel B). The bottom 99% experienced no real growth in wage income since 1972, and the pattern of changes in real wages does not seem to be related to changes in marginal tax rates. In contrast, top 1% wage income earners experienced accelerating growth over the 1960 to 2000 period, with almost a tripling in real wage income since the early 1970s. Consistent with the pattern of the wage component for overall income, top wage incomes experienced spikes just after TRA 1986 and just before OBRA 1993, clear evidence of short-term responses (or re-timing) of labor income compensation. However, the long-run pattern seems to be an extraordinary and accelerating growth independent of the tax developments, as marginal tax rates on those wage income earners were about the same, around 40%, in the mid 1960s and in the most recent years. Indeed, the secular growth in top wages starts in the early 1970s, a time when marginal tax rates were actually increasing (due mostly to bracket creep). To understand better this unprecedented increase in top wage incomes, it is useful to consider smaller groups within the top 1% as we did for overall income.

⁵⁷As described in Slemrod (1994), due to the interaction of this provision with the regular schedule, the marginal income tax rate on labor income could be higher than those limits in a number of cases.

Table 5 produces the same regressions as Table 4 but for wage incomes instead of overall income.⁵⁸ The shares of the bottom groups of the top decile below the top 1% (top 10-5% and top 5-1%) display very low elasticities, while all groups within the top 1% display significant elasticities when no time trend is included, increasing sharply from 0.3 to 2.5 as we move up the wage income distribution. This is because all the increase in the top wage income shares is attributed to the secular decline in marginal tax rates since the 1960s. Including two time trends reduces significantly the estimated elasticities which are below 0.4 except for the very top groups. Even within the top 0.1%, where elasticities are sizeable, tax changes can only explain a very small fraction of the dramatic surge in top wage incomes.

The key point to resolve is whether we should attribute the long-term increase in top wage shares entirely to the long-term decrease in marginal tax rates. Comparing 1960 and 2000, that seems to be an untenable view for groups below the top .1% because those groups faced comparable marginal tax rates in 1960 and in 2000. As a result, the sizeable increase in the top 1-.5% and top .5-.1% wage income shares cannot be due entirely to marginal tax rates.

The problem is more complicated for the very top groups (within the top .1%) because those groups experienced much larger gains but also experienced a non trivial decline in marginal tax rates. Undoubtedly, a reason for the huge increase in top wage income shares (the top .01% share increased more than ten-fold from .21% in 1970 to 2.45% in 2000) has been the development of stock-options. Stock-options also create lumpiness in wage compensation as they are exercised by executives only once every few years. As a result, the top .01% might be extremely large in recent years because, in any given year, very top wage earners are executives who happen to exercise their stock-options in that particular year. The stock-option phenomenon, however, has clearly increased the average compensation of top executives as the top 1%, which certainly includes virtually all the top employees receiving large option grants, even when they do not exercise stock-options, more than doubles from 5.1% to 12.6% from 1970 to 2000.

Thus, the extraordinary increase in top wage incomes, a phenomenon certainly closely related to the explosion of the compensation of CEOs and other top executives, sports, movies, and television stars, appears too large to have been solely the direct consequence of the tax reductions

⁵⁸We have omitted the IV estimates in the case of wages because the first stage is not as strong as in the case of income and the estimates are more noisy.

through supply-side effects. Furthermore, the surge in top wages is not related closely enough to the timing of the tax cuts to suggest a direct and simple causal link. Particularly surprising is the surge in top wages since 1994, in spite of the significant tax increase in 1993, which makes the secular reduction in marginal tax rates faced by top wage groups appear rather small.⁵⁹

A more pertinent question to ask is perhaps whether this surge in top wages could have occurred, had the tax structure remained the same as in the early 1960s, and the working rich had to pay in taxes more than three quarters of their compensation. It is plausible to think that the drastic reduction in top marginal tax rates, which started in the 1960s, opened the possibility of the dramatic increase in top wages that started in the 1970s, and accelerated in the 1980s and the 1990s. It is of course impossible to provide a convincing answer to that important question by looking only at individual income tax statistics in the United States. A promising way to make progress would be look more closely into the top salaries surge phenomenon by analyzing executive compensation data. There is a large literature on executive compensation (see Murphy, 1999 for a survey). However, although there are many studies explaining disparity of CEO pay in cross-sectional data, no convincing explanation for the time series evidence seems to have been provided.⁶⁰ If the dramatic surge in top compensation is not fully explained by a comparable surge in the marginal productivity of top executives, then this is evidence of a market failure which would certainly change the welfare and tax policy analysis that we presented above. Alternatively, top executive pay may now be aligned to marginal product and was below market value before. We note, however, that the surge in the top 1% salaries since the early 1970s has been accompanied with a dismal growth for the bottom 99% salary earners, and thus does not seem to have had a positive impact on the vast majority of working families. An alternative way to make progress in our understanding is by looking at other countries experiences, a point to which we now turn for our conclusion.

⁵⁹Companies, however, might have started granting stock-options more aggressively after TRA 1986 because of the decrease in individual tax rates. Those options can be exercised (and thus appear on individual income tax returns) only a number of years later. Hall and Murphy (2003) show, however, that grants of stock-options, valued using the Black-Scholes formula, increased massively *after* the tax increase of 1993.

⁶⁰It is quite telling to read in the recent survey of Hall and Murphy (2003), two prominent and conservative researchers in this field, that their best explanation for the surge in stock-option compensation was that “boards and managers falsely perceive stock options to be inexpensive because of accounting and cash-flow considerations”.

4 Conclusion: International Comparisons

Unfortunately, no other country offers such a large body of empirical analysis on behavioral responses to individual income taxation than the United States. Recently, however, a number of studies have produced series of top income shares using tax return data. Although, those studies do not produce corresponding series of marginal tax rates, as we have done here, interesting findings emerge.

First, there is enormous heterogeneity in the behavior of top income shares in the recent decades across countries. Some countries, such as the United Kingdom (Atkinson, 2002) or Canada (Saez and Veall, 2003) have experienced notable increases in top income shares, although those increases have not been as pronounced as in the United States. In contrast, countries from continental Europe such as France (Piketty, 2001), the Netherlands (Atkinson and Salverda, 2003), or Switzerland (Dell, Piketty, and Saez, 2003) have experienced either declines or little changes in top income shares since the 1960.

Second, the United Kingdom experience seems to be the closest to the U.S. experience. Top income shares in the United Kingdom started increasing exactly in 1979 when the top rate declined from 98% to 75%, although this increase seems modest relative to size of net-of-tax increase at the top.⁶¹ In 1988, the top rate was further decreased to 40% and has not changed since then. In contrast to the United States however, the increase in top share has been relatively smooth since 1979 with no break around the tax changes. Studying the composition, and estimating precisely the marginal tax rates faced by top U.K. incomes seems to be a priority to understand whether the recent increase in top incomes is due to the tax developments.⁶²

Third, Canada has experienced a surge in top incomes significantly larger than the United Kingdom (although smaller than the United States), and as in the United States, this increase has been due to a dramatic increase in top salaries since the early 1980s. However, in contrast to the United States, top incomes in Canada have not experienced, very large tax cuts since the 1960s.⁶³ Thus, the dramatic increase in top incomes in Canada cannot be attributed solely to

⁶¹It might be the case, however, that for the top .1% incomes, the average decline in marginal tax rates has been much more modest.

⁶²Dilnot and Kell (1988) try to analyze this issue but have only access to a single year of micro-tax returns and have to rely on aggregate numbers for their time series analysis.

⁶³The top income tax rate in Canada, including provincial taxes, is about 50% in 2000.

fiscal developments in Canada. Saez and Veall (2003) argue that the threat of emigration toward the United States have forced Canadian companies to increase the pay of their top employees to retain them, thereby replicating in Canada the dramatic U.S. increase in top employees' pay. If the migration threat explanation is correct, it implies that the surge in top wage incomes in the United States is a real phenomenon and not uniquely a consequence of repackaging of income in order to avoid taxes.

Last, in contrast to the United States and the United Kingdom, France, Netherlands, and Switzerland have experienced relatively small changes in their top tax rates. Piketty (1999) shows that the small changes in the French top tax rates generated small short-term responses of top incomes but that those responses do not seem to persist overtime. Switzerland has lower top income tax rates than the United States (around 35% when adding federal, cantonal, and local income taxes), but has much lower top income shares than the United States (the top 1% share is around 8-9% in the 1990s, while it is between 13 and 17% in the United States).

In sum, high income tax rates do not seem to be able to account for the differences in top income shares across countries, although it is more debatable whether they can account for a substantial part of the time series pattern within countries. Therefore, it would be of most interest to make a systematic analysis of top incomes in countries which have experienced drastic cuts in top income tax rates in the recent decades, as in the United States and the United Kingdom. Those results could teach us whether a dramatic cut in top rates is necessarily associated with a rise in top incomes.

FIGURE 2.

Marginal Tax Rates and Average Real Incomes for the Bottom 99% and the Top 1%

Source: Series obtained from Tables A and B1

A. Top 10-5% tax units

B. Top 1-5% tax units

FIGURE 3.

Tax Rates and Income Shares for the Medium-High Income Groups

Source: Series obtained from Tables B1 and B2

FIGURE 4.
Tax Rates and Income Shares for the Very Top Groups

Source: Series obtained from Tables B1 and B2

FIGURE 5.

The Top 1% Income Share and fitted Values from Elasticity Regressions

Source: Series based on regression analysis presented in Table 3, columns (1) and (5).
 The diamond line is the top 1% income share. The dotted line is the fitted regression curve including only the net-of-tax rate. The solid line is the fitted regression curve including time controls. The dashed line is the same fitted regression curve but freezes the marginal tax rate at the 1960 value.

FIGURE 6.

The Top 10% Income Share and Composition, 1960-2000

Source: Tables B1 and Table D1 in the working paper version Saez (2004).

The figure displays the income share of the top 10% tax units, and how the top 10% incomes are divided into seven income components: wages and salaries (including exercised stock options), S-corporation profits, partnership profits, sole proprietorship profits, dividends, interest income, and other income.

FIGURE 7.

The Top 1% Income Share and Composition, 1960-2000

Source: Tables B1 and Table D1 in the working paper version Saez (2004).

The figure displays the income share of the top 1% tax units, and how the top 1% incomes are divided into seven income components: wages and salaries (including exercised stock options), S-corporation profits, partnership profits, sole proprietorship profits, dividends, interest income, and other income.

FIGURE 8.

The Top 0.01% Income Share and Composition, 1960-2000

Source: Tables B1 and Table D1 in the working paper version Saez (2004).

The figure displays the income share of the top .01% tax units, and how the top .01% incomes are divided into seven income components: wages and salaries (including exercised stock options), S-corporation profits, partnership profits, sole proprietorship profits, dividends, interest income, and other income.

A. Bottom 99% tax units with wage income

B. Top 1% tax units with wage income

Marginal Tax Rates and Average Real Wage Incomes for the Bottom 99% and the Top 1%

Source: Series obtained from Tables A, C1, and C2.

TABLE 1.
Thresholds and Average Incomes in Top Income Groups in 2000

Percentile threshold (1)	Income threshold (2)	Income Groups (3)	Number of tax units (4)	Average income in each group (5)
		Full Population	133,589,000	\$42,709
Median	\$25,076	Bottom 90%	120,230,100	\$26,616
Top 10%	\$87,334	Top 10-5%	6,679,450	\$100,480
Top 5%	\$120,212	Top 5-1%	5,343,560	\$162,366
Top 1%	\$277,983	Top 1-0.5%	667,945	\$327,970
Top .5%	\$397,949	Top 0.5-0.1%	534,356	\$611,848
Top .1%	\$1,134,849	Top 0.1-0.01%	120,230	\$2,047,801
Top .01%	\$5,349,795	Top 0.01%	13,359	\$13,055,242

Notes: Computations based on income tax return statistics.

Income defined as annual gross income reported on tax returns excluding capital gains and all government transfers (such as Social Security, Unemployment Benefits, Welfare Payments, etc.) and before individual income taxes and employees' payroll taxes. Amounts are expressed in current 2000 dollars.

Column (2) reports the income thresholds corresponding to each of the percentiles in column (1). For example, an annual income of at least \$87,334 is required to belong to the top 10% tax units, etc.

Notes: Population and tax units estimates based on census and current population surveys (Historical Statistics of the United States, and Statistical Abstract of the United States)
 Tax units estimated as sum of married men, divorced and widowed men and women, and singles men and women aged 20 and over.
 Income defined as Adjusted Gross Income less realized capital gains, taxable SS and UI benefits and adding back all adjustments to gross income. Income of non-filers is imputed as 20% of average income.
 Marginal tax rates are weighted by income and estimated using TAXSIM calculator and the tax return micro-files and ignoring interactions with state income taxes.
 Marginal income tax rate in column (10) is a weighted average of marginal tax rate on earned income and other income.
 Tax units with wages defined as total number of employees (from National Income and Product Accounts) less number of married women employed (from Statistical Abstract of the United States).
 Total wages from total compensation of employees from National Income and Product Accounts.
 Marginal income tax rate in column (14) is the average (wage income weighted) marginal tax rate on wages and salaries.
 Consumer Price Index (CPI-U) is the official CPI index from Economic Report of the President. CPI-U-RS includes retrospectively improvements on CPI estimation method for 1967-1998 period.

Notes: Computations by authors on tax return statistics. Taxpayers are ranked by gross income (excluding capital gains and government transfers). Income of non-filers is imputed as 20% of average income. Groups defined relative to all tax units (filers and non-filers). The Table reports the percentage of total income accruing to each of the top groups. Top 10% denotes to top decile, top 10-5% denotes the bottom half of the top decile, etc.

Table B2. Marginal Tax Rates for Top Income Groups in the United States, 1960-2000

Notes: Marginal Tax Rates computed using micro-files of tax returns and the TAXSIM calculator. Marginal tax rates include only federal income taxes and ignore state income taxes. Marginal tax rates are weighted by income, and are a weighted average of marginal tax rates on earnings and other income (excluding capital gains).

Column (12) reports the top marginal tax rate. In 1960-1963, the top bracket rate is 91% but there is maximum average tax rate of 87%.

In 1971-1981, the top marginal tax rate for labor income is lower (see Table D2).

Notes: Computations by authors on tax return statistics. Taxpayers are ranked by wages and salaries (which includes exercise of stock options).

Groups are defined relative to all tax units with wage income (filers and non-filers).

The Table reports the percentage of total wages and salaries accruing to each of the top groups. Top 10% denotes to top decile, top 10-5% denotes the bottom half of the top decile, etc.

Table C2. Marginal Tax Rates on Wages for Top Wage Income Groups in the United States, 1960-2000

	Top 10%	Top 5%	Top 1%	Top .5%	Top .1%	Top .01%	Top 10-5%	Top 5-1%	Top 1-.5%	Top .5-.1%	Top .1-.01%	Top MTR

Notes: Marginal Tax Rates on wage income are computed using micro-files of tax returns and the TAXSIM calculator. Marginal tax rates include only federal income taxes and ignore state income taxes, as well as payroll taxes. Marginal tax rates are weighted by wage income.

Column (12) reports the top marginal tax rate on labor income. In 1960-1963, the top bracket rate is 91% but there is maximum average tax rate of 87%.

In 1971-1981, the top marginal tax rate for non-labor income is 70% (see Table B2) and the labor income marginal tax rate can be locally larger than reported.
